There are many points of interest in this case which, for want of space, cannot be considered. Gastric catarrh had lasted so long that the patient had become accustomed to symptoms which should have caused constant alarm. The ulcer seems never to have been suspected by any of the numerous physicians he had consulted, and it is, of course, idle to speculate as to its duration, or as to whether it might have been recognized if the case had been studied carefully with suspicion alive, as it should always be where recurring pain and vomiting occur. His straight abdominal muscles were enormously developed, but the lesions about the duodenum indicated that, with proper care, the local thickening and hardening might have been detected.

All of these cases illustrate the difficulty of the treatment of simple ulcer of the stomach or duodenum. It is clear that, whenever suspicion is aroused as to the existence of ulcer, treatment must be prompt, rigid and persistent. Even when symptoms are mild, the gravest danger is lurking in the case. Taken thus, most cases recover. Strict rest; rigidly regulated feeding; full courses of nitrate of silver, alternating with oxalate of cerium, with bismuth or with copper, seem the most important elements of treatment. Careful attention to coexisting gastric catarrh by diet, by mild mineral waters, or even by lavage, may be demanded. Complications and accidents must be met promptly. Even the gravest cases may terminate favorably, after recovery seeming wellnigh impossible; so that the prognosis must not be a hopeless one as long as life lasts. The disease affords a good field for, and at times most imperatively demands, judicious hypodermic medication and rectal alimentation. The value of the latter cannot be exaggerated. In very bad cases, it may be associated with systematic inunction, and, as shown in Cases 2 and 3, life may be thus sustained for long periods, until happily the progress of cicatrization permits the resumption of feeding by the mouth.

THE TREATMENT OF ASTHMA.

Portion of a Lecture delivered in the Regular Course of 1885-86.

BY N. S. DAVIS, JR., A.M., M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE IN THE CHICAGO MEDICAL COLLEGE, PHYSICIAN TO MERCY HOSPITAL, ETC

For the relief of asthma an almost countless number of drugs have been suggested and tried. It is not my purpose even to enumerate these, but to call attention to those that are to-day most frequently employed with success and to those with which I have had personal experience. Treatment of asthma is prophylactic and also is addressed to the immediate relief of the dyspnea. In order to understand the mode of action of drugs in asthma, it is necessary to keep in mind its causes and the mechanisms within the body that are called into play in producing the phenomena of the disease. It is true that the bronchial tubes are congested during the dyspneic attacks, but it is not probable that this is the cause of the difficulty of breathing. A true spasm of the bronchioles constitutes the essential change. This spasm is produced by contraction of the muscular tissue in the bronchial wall when excited by the nerves supplied to it. The initial irritation of the nervous system arises in only a moderate proportion of all cases within the bronchial tubes. In some cases of bronchitis, and in some cases of uncompensated heart disease with passive engorgement of the bronchial vessels the afferent nerves of the bronchi are irritated, and thus reflexly the efferent nerves and finally the bronchial muscles are excited. Immediate irritation of the efferent nerves may be the cause of spasm of the bronchi in these cases, although the action of drugs points to a reflex cause. More frequently the initial irritation is in some distant organ, whence reflexly the muscular nerves of the bronchi are excited. A common illustration of this mode of origin of bronchial spasm is seen in the cases of hay and rose fever that are complicated by asthma. The initial irritation is within the nose. In rare cases we find the efferent nerves to the bronchi excited by mental changes or changes originating within the central nervous system. In mild uræmic poisoning asthma occasionally occurs. Whether, in these cases, the uræmic poison primarily irritates the central nervous system and thus provokes the attack, or the peripheral nerves and bronchial muscles, is not known, but the former explanation seems probable. The mechanism, as you will notice, essential to the production of most asthmatic attacks, consists of the afferent nerves and primary irritation of their termini, of nerve centres, probably in the medulla, by which the irritation of the afferent nerves is reflected to the efferent nerves and, lastly, the efferent nerves and their endings in the muscles of the bronchi. For convenience we may name the first of these factors, the afferent nerve endings, the *source of irritation*; the second, the

nerve centre, the *reflector*; and the third, the efferent nerves and bronchial muscle fibres, the *focus of irritation*.

An analysis of the mode of action of the drugs that are most successful in asthma shows that in one of three ways they relieve the spasm. We may therefore place them in three groups. These groups are characterized by the mode of action of the drugs upon the nervous mechanism involved in asthma. The first includes those that affect the source of irritation and thus prevent the development of an attack; the second those that benumb the nerve centre or reflector of irritation; and the third those that act upon the focus of irritation.

In the first group we must place a very promising collection of drugs, since the source of irritation may be in almost any part of the body. We find, therefore, in this list, those medicines that allay irritability of nasal, pharyngeal, bronchial and gastric mucous membranes, and also those that allay irritability of the womb and some of the parenchymatous organs.

A very considerable number of cases have for the source of irritation the nasal mucous membrane. The irritant may be a foreign body in the air that is breathed, or a chronic inflammation of the mucous membrane, or a polypoid or other growth. Prophylaxis is readily applied to the cases of hay fever, in which foreign bodies in the atmosphere are the exciting cause and the nasal mucous membrane the source of irritation of the disease and complicating asthma. A change of climate and therefore of air is curative. The localities in this country that afford most perfect exemption are the White Mountains, Mackinac and many localities along the shore of Lake Superior, and numerous places in the more elevated parts of the Rocky and other mountainous regions. A residence in the heart of a thickly populated city will often grant to individual cases immunity, although they may suffer severely in neighboring suburbs. As these attacks are most likely to occur at certain seasons, especially in August and September and less frequently in June, temporary changes of abode at these times will usually give to those who are liable to the attacks exemption. Many of the afflicted cannot take advantage of such prophylactic treatment. It is possible, usually, to lessen the severity of attacks and sometimes to prevent them by appropriately applied medicinal treatment. There is necessary for the production of this asthma not only the specific irritant in the atmosphere, but a peculiar sensitiveness of the nerve endings which constitute the source of irritation, and possibly also of the nerve centres. Advantage can be taken of these facts in mitigating and preventing the disease when a change to a pure unirritating air is impossible. Thus, in hay fever, local anaesthetics applied to the nasal mucous membrane will frequently

hold the disease in abeyance or at least mitigate it. Of the remedial agents that can be topically applied for anæsthetic effects, cocaine is the most important. A 5 to 10 per cent. solution may be sprayed into the nose through the anterior nares and, when necessary, also applied to the posterior nares through the mouth. Or it can be employed by insufflating a powder composed of it and some bland diluent. A cocaine ointment may be used, a little being placed in the nostrils and allowed to melt and trickle backwards so as to anoint the mucous surfaces. This method is less efficacious than either of the others, since the drug is not applied so uniformly to all parts of the nose. It must be remembered in regard to cocaine that, if used in small amounts often, or in strong solution less frequently, symptoms of intoxication may be produced. I have rarely found it necessary to use preparations of more than 4 per cent. strength. Often a few applications of cocaine will greatly aid in discovering the source of irritation, for cases occur in which we suspect the source to be in the nose or throat, and if applications to these parts allay the dyspnoea, we may feel that our suspicions are well founded.

As a topical application morphia is also useful. It acts less promptly than cocaine, but often its effects are more lasting. A favorite formula of mine consists of 4 per cent. of cocaine, 2 per cent. of morphia, mixed with some inert powder or with water, according as I wish to make applications by insufflating or by spraying.

To prevent asthmas that result from the existence of chronic inflammation or tumors within the nostrils a destruction of the irritating tissue must be effected. A temporary relief can often be obtained by the use of the local anæsthetics just mentioned. Rarely the source of irritation is found in the pharynx or larynx. In such cases the irritant is usually a morbid growth or a chronic inflammation with hypertrophy. Such lesions must be treated just as are their analogues in the nasal cavity.

We must place in this miscellaneous group also the various expectorant and anodyne mixtures that are employed to allay laryngitis, trachitis or bronchitis, since these inflammations are frequent causes of asthma, and therefore their cure will give exemption. The efficacy of such mixtures is greatly enhanced by combining with them drugs that belong to the second group, or those that allay the excitability of the reflex centres.

In the same way asthma which accompanies uncompensated valvular disease of the heart is relieved by digitalis and similar drugs. They strengthen the heart's action and give greater tone to the blood-vessels, and thus reduce venous hyperæmia of the lungs and bronchi. These remedies accomplish more for such asthmatics than those that relax muscular spasm. They do good by stopping the irritation at its source.

Cases in which the source of irritation is in the organs of the alimentary tract are relieved, and often permanently cured, by treatment of the primary lesions. Occasionally a woman is found who is persistently troubled with asthma during pregnancy, although free from it at other times. Absolute relief is, so long as pregnancy lasts, usually impossible. I have, however, seen most marked benefit obtained by the persistent use of viburnum prunifolium. This drug without doubt lessens the irritability of the uterine tissues, and thus diminishes the irritability of the source of irritation of the asthma.

The second group of drugs includes those that act on the nerve centres and thus inhibit reflex action. The most important of them are chloral, chloroform, ether, opiates and bromides. When dyspnoea is intense a few whiffs of chloroform will give relief promptly. As the relief is often not of long duration and as the drug cannot with safety be left in the hands of the sufferer, its range of usefulness is limited. Of this group, chloral is the safest and most universally useful. If the asthma is wholly paroxysmal, it is best administered in one or two full doses rather than in several smaller ones. Often 1 gram or 1½ grams, given in sweetened water, will not only relieve present dyspnoea but produce an effect sufficiently lasting to suppress the attack. In cases that occur as complicating bronchitis, trachitis or laryngitis, and in which the dyspnoea is not paroxysmal only, but to some extent is persistent, since the source of irritation is constantly excited, the best effects are to be obtained by the repetition of smaller doses of chloral or of bromides, or of opiates, or of mixtures of all these with expectorants. In this way the nerve centres are constantly inhibited or restrained in their activity, so that the paroxysms of exacerbation are held in abeyance and time is gained in which to overcome the primary inflammation. A formula that I have frequently employed with marked benefit in such cases is the following:

R. Chloral	grams 15.00.
Ammonii muriatis.	" 10.00.
Morphice muriatis.	" .20.
Antim. et pot. tart.	" .15.
Ex. grindelie robustae fl.	" 45 vel 60.00.
Aq. vel syr. glycyrrhiz q. s. ad.	" 120.00.

Give 1 teaspoonful every three to six hours in sweetened water.

Morphia and the bromides are less generally useful than chloral. The bromides, given steadily in rather large doses, are serviceable when the source of irritation is the larynx or pharynx, for they not only act favorably by lessening the excitability of reflex centres, but also have the peculiar property of benumbing the nerve endings in the mucous membrane of the larynx and pharynx. The dose should be large, for example, 1½ to 3 grams of the bromide of sodium.

There is another class of remedial agents which

it is difficult to classify with certainty, for our knowledge of their physiological action is imperfect, and the results of researches are not completely harmonious. The drugs to which I refer are *grindelia robusta*, *senecio aureus*, *quebracho*, *lobelia*, *tobacco*. It seems probable, however, that as remedies for asthma they can be placed in this second group. The last of these we know produces its nauseant effects chiefly by acting on the nauseating centre in the medulla. Death from tobacco poisoning is due to paralysis of respiration. The end organs of the motor nerves are first affected, then the nerve trunks, and finally the respiratory centre. The physiological action of *lobelia* is very similar to that of *tobacco*. When *lobelia* is used in asthma it must be given in doses of from 2 to 4 cubic centimetres of the tincture, and repeated every two hours or oftener until vomiting and relief are produced. Mitigation of the dyspnoea usually corresponds with intense nausea and is greatest after vomiting.

Tobacco is useful only in mild cases, and when used by persons not accustomed to it. From the apparent relation of the therapeutic effect to the nausea, the action of the drugs seems to be due to an influence which they exert upon the respiratory and vomiting centres. It is not possible that their therapeutic action is due to paresis of the motor nerves, for it is only by overwhelming doses that these nerves are paralyzed. *Tobacco* and *lobelia* do not affect the muscle fibres. It must be remembered, too, that during intense nausea from any cause respiration becomes deeper and more forceful. From all these considerations, I feel inclined to ascribe their favorable action to the influence they exert over the reflex act at the nerve centre.

Quebracho has a peculiar effect upon respiration in healthy persons. It slows it and prevents panting when hurried movements are made. At the same time it retards the heart. Gutman has shown that its active principle, *aspidospermine*, produces death by poisoning the respiratory centre.

We know less of the physiological action of *grindelia* and nothing of *senecio*. *Grindelia* produces death only in very large doses, and then by paralyzing respiration. In smaller doses it slows the respiration and the heart.

The effects of *lobelia* must be carefully watched, for large doses have produced alarming symptoms. For this reason I have employed it rarely, but *grindelia* I have administered frequently and *quebracho* and *senecio* less frequently, although enough to feel confident that to some extent they are useful. They are so much less efficacious than some other remedies at our command for the relief of the dyspnoea that I rely upon them not at all for its treatment, but rather as adjuvants for warding off the recurrence of the paroxysms.

Grindelia and *quebracho* are probably mildly expectorant, and through their bitterness tonic to

the stomach. I have seen several cases apparently exempted from severe attacks by *senecio aureus* only. The drug was not given during dyspnoea, but while the paroxysms were threatening and at a season when the patients were usually afflicted by them. By the continued use of it for several weeks an actual outbreak was avoided. *Grindelia* and *quebracho* are the most efficacious of these remedies. But their bitter and otherwise unpleasant taste limits greatly their eligibility. Their fluid extracts can be administered in doses of 2 to 4 cubic centimetres.

The third group of drugs embraces the nitrites and nitro-glycerine. Amyl nitrite administered by inhalation has been used in asthma for a number of years. Nitro-glycerine has been used less frequently, and the nitrites of soda and potash still less. Prof. Fraser, of Edinburgh, has given us the most trustworthy information as to the relative value of these drugs in asthma. They all relieve the spasm, and with wonderful promptness. The effects of amyl nitrite are very transitory. Nitro-glycerine, when given in doses of sufficient size, is apt to provoke congestive headache. The nitrite of soda he found gave quite as prompt relief as the others, was less likely to provoke headache and produced more enduring effects. The more purely spasmodic the case the more efficacious are these drugs. Dr. Fraser found that in two or three minutes after the administration of even half grain doses of the nitrite of soda, marked relief was noticeable in the patient's breathing and a lessening of the crowing and piping in the chest. In ten minutes or less, as a rule, the patients feel comfortable. It was rare that it was necessary to repeat the dose in any single attack. The good effect of these drugs, when administered in the usual therapeutic doses, is undoubtedly chiefly due to their action upon the muscle fibres of the bronchial tubes, irritability of which they lessen or temporarily destroy. In other words, they act upon the focus of irritation. In less degree they may diminish the irritability of the motor nerves. This is a somewhat doubtful effect of therapeutic doses, although it can be obtained from large doses. Very large doses also lessen the excitability of the spinal cord and higher nerve centres. In using the nitrite of soda, which from considerable personal experience I can commend, it must be remembered that there are two preparations in the market, a "commercial" and a chemically pure. The former can be given in doses of from 5 to 10 grs. (gms. .3 to .6), and 20 grs. (gms. 1.3) have been given without harm.¹ The therapeutic dose of the chemically pure drug is from 1 to 5 grs. (gms. .06 to .3). Headache, although of rare occurrence from the nitrite of soda, is not always wanting. During the present fall, in the case of Mrs. C., I directed 6 decigrams of the commercial nitrite to be taken. It relieved

¹ "Therapeutics, its Principles and Practice," by H. C. Wood.

the dyspnoea promptly, but produced an intense though temporary headache. While the most beneficial effects are obtained in the most frankly paroxysmal cases, I have derived marked benefit from the continued use of these remedies in asthma but complicated bronchitis and that were to some extent persistent. In such cases I have combined the nitrite of soda with the usual expectorant and anodyne treatment of bronchitis. I have administered it in 18 to 30 centigram doses every three to six hours. While it does not influence inflammation or allay cough, it seems to lessen the dyspnoea and prevent the paroxysmal exacerbations which recur in such cases.

Atropia, stramonium and hyoscyamus constitute another series of drugs that are analgesic to the focus of irritation. The two first are the ones most frequently used in this disease. They cause relaxation of the bronchioles, in part by benumbing their involuntary muscular fibres and in part by lessening the sensibility of their terminal nerve fibres. While efficient in aiding to give relief, their side effects are so marked and often so disagreeable that they cannot be used in efficient doses. The action of the drugs is so well known that I need hardly say that these side effects are dryness of the mouth and throat and heat and redness of the skin, dilatation of the pupil, disturbed vision and, in very susceptible patients, mental disturbances. I have rarely employed these remedies in the full doses that are necessary in order to obtain the best results in asthma, but frequently use them in smaller doses to reinforce the action of other drugs. A favorite and very efficient combination for the relief of asthmatic dyspnoea I have found to be:

R. Chloral	grams	20.
Sodium nitrite	"	3.
Tinct. stramonium	"	10.
Elix. simpl. q. s. ad	"	60.

Take 1 teaspoonful every four hours in water.

Not only do these remedies act favorably when they are taken by the stomach, but the inhalation of the smoke of the crude drugs is often of the greatest benefit. Stramonium leaves are used in this way most frequently. The leaves are smoked either when rolled into cigarettes or from a pipe. Their efficacy is enhanced by first soaking them in a saturated solution of nitre and subsequently drying them for use; or they may be mixed with or rolled in bibulous paper that has been thus saturated. The nitre is decomposed by the heat and a nitrite is formed which aids in relieving the dyspnoea. There are numerous proprietary cigarettes and pastels for asthma, the basis of whose composition is stramonium and nitre.

Rarely examples of a peculiar form of asthma are seen in which the source of irritation seems to be mental or central rather than peripheral. I refer to those cases in which the dyspnoea is caused by fear, and to those in which it is excited by cer-

tain but the most varied localities or odors. If these susceptible persons are not conscious of being in the locality of the noxious object no respiratory discomfort is experienced. These are cases of mental idiosyncrasy, and usually occur in persons of an hysterical temperament. It is in such cases that valerian has sometimes been used with benefit.

Asthma occurs as a frequent complication of Bright's disease. It is caused in two ways by this disease. In some cases it arises from a complicating bronchitis, but more frequently from uræmic poisoning. When bronchitis is the cause it must be treated upon the principles already explained, but when uræmia is present a different method must be employed. The measures that are most beneficial are those that aid in eliminating the poison. Diaphoretics, diuretics and cathartics are therefore indicated. The first of these classes of drugs gives the most prompt relief. Of diaphoretics, pilocarpine administered subcutaneously is the most prompt in its action. The uræmic poisons are largely eliminated by the copious diaphoresis that it produces. It is necessary to prevent their reaccumulation. This is best accomplished by diuretics and, when they are not sufficient, the coincident use of cathartics. Cathartics and the preparation of jaborandi must be employed with much caution when a patient is debilitated or has heart weakness.

In the intervals between the dyspnoeic attacks the iodides are often prescribed, and with marked benefit. Unfortunately, they do not uniformly ward off or mitigate the paroxysms. Clinicians have not yet discovered the precise indications for their use. The cases in which I have most uniformly derived good results from their employment have complicated chronic bronchitis. It is probable that their good effects are largely due to the property which they possess of promoting reabsorption of cellular exudates into inflamed tissues. The iodide of soda is the most eligible preparation for persistent employment. It should be given for weeks and often for months.

There have been observed rarely cases in which the asthma seemed due to direct irritation of the pneumogastric nerve by enlarged bronchial and cervical glands. In a few of these cases the iodides are said to have done good by reducing the glandular enlargement.

Arsenic is also frequently administered persistently in the intervals between paroxysms. How it acts we do not know. It is a remedy, as you remember, that is employed for the relief of many paroxysmal neuroses. The Fowler's solution, administered in gradually increased doses up to the point of toleration and then persistently continued, is perhaps the favorite prescription. Personally I have not been gratified with the results that I have obtained from its use.

ORIGINAL ARTICLES.

MICRO-ORGANISMS; AND THEIR RELATION TO DISEASE.

Read before the American Academy of Medicine, and approved by the Council for publication.

BY SAMUEL N. NELSON, A.M., M.D.,

OF BOSTON, MASS.

SURGEON TO THE SOLDIERS' HOME IN MASSACHUSETTS

The rôle of the microorganisms called bacteria is at present probably occupying the attention of more scientific men than any other subject in modern science. Great numbers of observers are at work on both continents in the solution of the *germ theory of disease*. Comparatively unknown till within a few years, on account of their very minute size, these microorganisms attracted attention and experimentation chiefly when the improvement of the microscope allowed objects of their size to come within the limits of its powers of observation. At first simply recognized as existing, their persistence and universality demanded question as to what they are, their origin and object.

The history of these microorganisms is related to that of spontaneous generation, to that of the fermentations, to the pathology and therapeutics of a great number of virulent and contagious affections; and in a more general manner to all the unknown, which notwithstanding the efforts of modern science still surrounds the origin of life and its preservation.

The bacteria are the lowest of organisms, belonging to the vegetable kingdom and are thus defined by the botanists, who have most recently occupied themselves with them: "Cells deprived of chlorophyll of globular, oblong or cylindrical form, sometimes sinuous or twisted, reproducing themselves partly by spores and by transverse division, living isolated or in cellular families, and having affinities which approach them to the algæ, and especially to the oscillariæ."

The atmosphere transports myriads of microscopic plants and animals. M. Miquel has pursued interesting studies upon them. M. Pouchet has devised the *aëroscope*, that bears his name, for collecting dust from the air which contains remnants of articles that we use, existing in the condition of impalpable dust, also pollen of plants, particles of mineral matter, and the spores of cryptogams, the moulds and algæ. Some micrographers have suggested that germs may be transported by the vapor of water; but Miquel's experiments show that the evaporation of water from the ground never carries any schizomycetes with it. On the other hand, dry dust, especially from hospitals, etc., is charged with microorganisms. The greatest labors, however, have been employed concerning a different class of organisms than the algæ and moulds. The plants

comprising this group, under the common designation of *bacteria*, in consequence of their extreme minuteness and refractive power, are invisible in the preparations of the *aëscopes*, and are recognized only by the higher powers of the microscope.

The first observer who recognized the microorganisms was Leeuwenhœck, as early as 1675. While examining with his magnifying glasses a drop of putrid water, the father of microscopy remarked with profound astonishment that it contained a multitude of little globules which moved with agility. During the following year he observed the presence of bacteria in feces and in tartar from the teeth.

M. Cohn is a naturalist who has occupied himself very much with the bacteria. In 1853 he published his first researches upon this subject and twenty years later there appeared a series of "Memoirs" devoted to these organisms. In the first paper he gives an exposition of his researches upon the organization, development and classification of the bacteria, and upon their action as ferments. His classification is:

1. The sphærobacteria, or globular bacteria.
2. The microbacteria, or rod bacteria.
3. The desmobacteria, or filamentous bacteria.
4. The spirobacteria, or spiral bacteria.

This classification has probably been accepted by more germ theorists of to-day than any other classification.¹

The smaller spherical bacteria may be confounded with various objects, *c. g.*, molecular granules, fat globules, amorphous precipitates, etc. To distinguish these pseudo-bacteria Nägeli says: "There are but three distinctive signs which enable us to recognize with some certainty that the granules under observation are organisms: spontaneous movement, multiplication, and equality of dimensions, united with regularity of form." To which may be added the action of re-agents.

The atmosphere is laden with these microorganisms. Developing in the organic infusions into which they fall, they soon determine their complete decomposition; for during their growth bacteria live upon the nutritive material, as all other plants do upon their soil. This is putrefaction, and they are always present as the cause. As is well known, bacteria are always present in some form or other in fermenting liquids. Fermentation only occurs after the access of particles from the outer world, and it is asserted by the supporters of the germ theory that these particles are organisms or their spores, and that it is by the growth of these organisms in the fermentescible material that it undergoes alteration. The essentials for the production of new forms are: a putrescible body, water

¹ The classification proposed by Koch is now quite universally accepted. The term *bacteria* is used in the general sense, including both the *micrococcæ*—the ball forms—and the *bacilli*—the rod forms.—Written since reading of the paper.

and air; while heat, light and electricity favor the process.

As Sir William Roberts says: "Without saprophytes there could be no putrefaction; and without putrefaction the waste materials thrown off by the animal and vegetable kingdoms could not be consumed. Instead of being broken up, as they are now, and restored to the earth and air in a fit state to nourish new generations of plants, they would remain as an intolerable incubus on the organic world. Plants would languish for want of nutriment, and animals would be hampered by their own excreta, and by the dead bodies of their mates and predecessors—in short the circle of life would be wanting an essential link. A large proportion of our food is prepared by the agency of saprophytes. We are indebted to certain bacteria for our butter, cheese, and vinegar. Our daily bread is made with yeast, and to the yeast plant (discovered in 1836 by Cagniard de la Tour, and also independently by Schwann about the same time) we also owe our wine, beer and spirituous liquors. As the generator of alcohol, this tiny cell plays a larger part in the life of civilized man than any other tree or plant."

Unfortunately for us, however, they have a powerful potency for evil also, and it is the noble aim of science to be able, by thorough study of the conditions under which that potency is acquired and exerted, to keep it under efficient control.

Much still remains to be determined with regard to the disease-producing possibilities of the germs that in invisible clouds drift in the atmosphere. The more delicate and exact methods of the most recent observers—Koch, Pasteur, Tyndall, Ehrlich, Ogsten, Sternberg and others—with regard to their nature seem to show that there are many varieties of them, each of which has its own conditions of growth, requiring or developing best in a particular soil. Different species multiplying in different media and varying in their susceptibility to different temperatures and to different chemical reagents. Apparent identity of form does not necessarily indicate identity of nature. They are not convertible into each other. Each species produces only itself, and is produced by itself alone, and when introduced into a substance that affords a favorable soil for its growth always produces the same results. These results are not produced suddenly, but are of gradual development, progressing with the slow and steady multiplication of the organism. They may be cultivated artificially in either solid or liquid media. The best known and most commonly used solid medium is nutrient gelatine, which unites the advantage of transparency with that of solidity; but it has the disadvantage of melting at a comparatively low temperature. When it is desired to cultivate bacteria at a temperature approaching that of the human body, sterilized blood-serum

may be used, or a preparation of agar-agar, a Japanese sea moss. The cut surface of a freshly sterilized boiled potato is also a very satisfactory culture medium under some conditions.

For liquid cultures a tube or bulb hermetically sealed, containing a sterilized infusion of hay or meat, is used, which will remain clear indefinitely. When, however, the germs are introduced in ever so minute quantity, they begin to develop, after a varying interval of one to twenty days, and then they rapidly increase. The liquid infusion, previously clear and pellucid, becomes more or less cloudy or turbid. When in this condition, we may be sure of the presence of rapidly increasing microorganisms in great numbers, as the microscope will invariably reveal.

It has been a widely disputed question as to whether bacteria ever occur in the animal in a perfectly healthy state: the affirmative view having been taken by Billroth and some others; but it is denied by Koch, by Pasteur and by Ehrlich, who state that they have never detected bacteria in the healthy animal. The failure of putrefactive bacteria, according to experiments, would go to show inability to struggle against the normal cells indigenous to the soil upon which they were planted. Some bacteria showed power of existence only in tissue in which vitality had entirely ceased, while others seemed to possess the power of existence in the presence of the animal cells when the latter suffered from impairment of nutrition, and the tide of life was turning against them. Abnormal composition of the blood seemed to favor the development of some bacteria, after they had found their way into the tissues.

The theory of a causal relation between bacteria and diseased processes has recently received a wide acceptance. In some diseases this relation is established, while in others it is presumed on the ground that bacteria are found in the blood and diseased products. As additional evidence in favor of special bacteria for different diseases, the fact is advanced that bacteria found in different diseases have been discovered to have different morphological and chemical properties; to which may be added of still greater value, the different appearances presented by the colonies growing upon solid culture media.

Admitting this causal relation of bacteria to disease, it must be demonstrated by successive cultures of the bacteria found to exist in the diseased person, and by the induction of the same disease in man or healthy animals by inoculation, with a reproduction of bacteria. The first discovery of the association of a germ with disease was by Pollender, in 1849, who found certain rodlets in the blood of animals suffering with splenic fever, also variously known as anthrax, wool-sorter's disease, malignant pustule, and

the parasite was afterwards pointed out by Davaine (1863), and subsequently carefully investigated and confirmed by Pasteur and Koch. The bacillus can be isolated and developed in proper cultivating media, and, when inoculated into some animals will produce splenic fever.

Again, in 1873, Obermeyer, of Berlin, discovered a bacterium in the blood of patients suffering from relapsing fever, which has been named *Spirillum Obermeyeri*. It is found only during the febrile paroxysm, disappearing during the interval. So far, attempts at cultivation have proved unsuccessful.

In March, 1882, Koch, of Berlin, announced the discovery of the *bacillus tuberculosis*, which he asserted to be the exciting cause of tuberculosis. His results have been confirmed by many observers, and the bacilli have been found in the tubercles and sputa of persons suffering from phthisis. As you all know, they reproduce themselves when cultivated under proper conditions, and cause tuberculosis when inoculated into animals.

The discovery of the parasitic origin of glanders followed closely upon that of the bacillus of tuberculosis. This was also made in Koch's laboratory by Prof. Schultz and Dr. Loeffler; and the results were verified by pure cultures and inoculations.

Birch-Hirschfeld has confirmed the discovery of the presence of a microorganism of syphilis, already announced by Aufrecht, which consists of oval-shaped micrococci in chains.

In gonorrhœa a micrococcus was discovered by Neisser, isolated, cultivated, and, it is reported, successfully inoculated.

Bacteria have also been found in malaria and in whooping-cough. A micrococcus has also been found associated with croupous pneumonia, by Friedlander. This may occur singly, but is generally found as a diplococcus.

Von Recklinghausen first described the bacteria of typhoid fever; and Klebs, in 1881, described a large bacillus, which he calls *B. Typhosus*, in which spores are formed in the centre, and often at the end. This is carried by the blood and lymphatics, and is found in all the organs. It is more generally believed, however, that the *causa morbi* is a peculiar short bacillus discovered by Eberth. This is rounded at both ends, and has spores. It is found in the ulcers, mesenteric glands and spleen; and has been cultivated by Gaffky. The inoculation of animals has not been successful; but it must be remembered that they do not have the disease spontaneously.

The *Micrococcus Vaccinæ* is very small, only half the thousandth of a millimetre in diameter, and is found isolated or in pairs, and when cultivated forms chaplets. Colin regards *M. Vaccinæ* and *M. Variolæ* as different races of the same species, but Magnin thinks them identical. In

vaccinia they are found in the lymph of the vesicle, and in its borders in the rete malpighi, and were subsequently traced into the subjacent cutis, especially in the lymphatic spaces. The multiplication and extension coincides with the development of the pustule. In variola, Chauveau (1868) first proved a particular nondiffusible active principle; and Cohn (1872) first proved that the lymph contains numerous micrococci. I have myself cultivated the *M. Vaccinæ* into the third generation in liquid media, the first inoculation being made directly from the lymph of the vesicles on a calf at Dr. Martin's stables in Roxbury; but limited experiments failed to produce characteristic vesicles on babies vaccinated from these cultures.

The comma bacillus of cholera (Koch, 1883) has of late attracted much attention. They are found chiefly in the excreta of cholera patients, are slightly curved like a comma or half of the letter U, and occur single or in pairs like the letter S; when their growth is retarded they form a spiral chain of several members. They are easily cultivated on nutrient gelatine, forming a growth easily distinguished from others, even from those which are morphologically similar, viz, the so-called cholera nostras, comma bacillus of Finkler and Prior, the mouth comma of Miller and the cheese comma of Deneke. After much experimentation Koch has succeeded in inoculating animals. The bacilli require an alkaline medium for their growth; so he injects, with a catheter carbonate of soda into the stomach of guinea pigs, to neutralize the acid of the gastric juice. Then he injects a considerable quantity of a solution containing the comma bacilli. Even this is not sufficient; for they pass through the intestines so quickly that they do not proliferate, and therefore he injects into the peritoneal cavity tincture of opium sufficient to paralyze the intestines and stupify the animal for some time. About half of the animals so treated die in from twelve to twenty-four hours, and a nearly pure culture of comma bacilli is found in the intestines.

In scarlet fever Coze and Feltz have found micrococci in the blood, and inoculation of rabbits sometimes produced death; but it is not certain that it was due to scarlatina. Polae Pineas found very minute micrococci on the scales of desquamating epithelium; and in the throat discharge.

In acute infectious osteomyelitis a peculiar micrococcus is found, which is easily cultivated, and, when rabbits are inoculated, and their bones broken, abscesses form containing micrococci.

In measles, Coze and Feltz found bacteria in the blood which were minute and mobile. The rabbits were not killed. Braidwood and Vacher caused children with measles to breathe through glass tubes coated with glycerine, and found sparkling bodies, something like those in vac-

cinia, but larger. These were most abundant during the second and third days. They also found them in the lungs and livers of two children who had died of the disease.

The individuals of the streptococci of erysipelas are smaller than the micrococci of vaccinia. Lukinsky found them in zooglea masses in the lymphatics, on the border of the erysipelatous zone. Fehleisen also found and cultivated them. He inoculated the ears of nine rabbits, and produced the characteristic rash in from thirty-six to forty-eight hours; the animals did not die. He also produced typical erysipelas, in from fifteen to sixty hours, in men who were inoculated to produce beneficial results in tumors. I have also cultivated them in liquid media.

Septicæmia and pyæmia have been carefully investigated by Koch; and these diseases have been found due to bacteria, which he has cultivated and inoculated.

In diphtheria, micrococci are found in the membrane and in the surrounding lymphatics, blood, kidneys and muscles. They are about the size of *M. Vaccinie*, slightly oval, single or in pairs, and in colonies. Eberth showed the particulate character by filtration. Klebs claims to have produced diphtheria from inoculation of pure cultures, and to have found micrococci in the tissues and blood. Nasiloff inoculated the cornea with enormous multiplication of microorganisms in the lymphatics of the palate, bones and cartilages, and says that they are the primary step.

With the diphtheria micrococcus I have had a personal experience. Some membrane was secured from the throat of a child during the operation of tracheotomy to relieve stenosis caused by diphtheria, and with it one of my hermetically sealed culture bulbs (made after Sternberg) filled with a sterilized nutrient fluid, was inoculated. On the fourth day the liquid, previously clear, became turbid, and, on examination with the microscope at about 1000 diameters, it was found swarming with micrococci in active motion about the size of the micrococcus of pus. In form they were slightly elongated, and although found singly, were generally in groups of three or four to eight or twelve. A second bulb was inoculated with a fraction of a drop from the first; it became turbid on the third day, and was found to contain a microorganism identical with the former. In this way about fifty bulbs were used, and the cultivation was carried through ten generations, each bulb becoming turbid on the third day, and the micrococci breeding true.

With the contents of one of the bulbs containing the sixth cultivated generation of the micrococci, six guinea pigs were inoculated in the cornea of the eye. One of them died about thirty hours later, with symptoms of blood poisoning; but the rest survived. The eyes became very

sore, the lids being much swollen and cedematous, and a membrane developed over the cornea. There was profuse discharge, which contained abundant micrococci. Three pigs were killed on the third day, and the eyes dissected for examination. The others were allowed to get well, but the eyes were completely destroyed. In the aqueous humor, and in the corner of the eyes examined, were found minute, highly refractive particles of uniform size, presumably micrococci. On the third day after killing the guinea pigs, I myself had a sore throat, and in twelve hours a large diphtheritic membrane had developed on the left tonsil, accompanied with high fever and constitutional symptoms. The disease ran a typical course, and convalescence was slow. Here, then, we have the chain of events complete. A fatal case of diphtheria, from which the germs were cultivated in pure cultures through ten generations, and the inoculation of the animals from which the experimenter himself contracted the disease with development of membrane containing micrococci, which reproduced themselves in cultures.

The question as to the origin of life has been much disputed, and the exponents of spontaneous generation and of the germ theory still continue the contest.

Extremists in the doctrine of evolution cannot sustain the hypothesis that the whole system of animal life is but a growth of one or more original species, changing into or evolving others through methods of development. The long ages of the past show the universality of the law of life, that like produces like.

Neither the agnostic nor the materialist can account for the origin of matter, much less can they account for the origin of mind. Naturalists tell us that while the animal and vegetable kingdoms are reducible to primoidal cells; that while there is a time when the embryos of species cannot be distinguished from each other by any essential features, yet the variety of structural forms, and the diversity of physiological functions which cells develop, are always according to the special type and construction of their parent cells; evidencing a unity of plan in their construction and development.

1. The germ theory asserts that no life has been evolved (except in the remotest periods of the earth's history) other than from a living parent or a living germ.

2. The spontaneous generation theory asserts that now, as of old, life does also spring *de novo* from molecular rearrangements of the atoms of dead organic matter.

No authority, except that of experimental work, can weigh a feather in the balance; no *a priori* reasoning can give the victory to either creed. The one condition is, to take dead matter, isolate it from all contact with life, place it

under favorable conditions for development, and watch the result.

The first views founded on experiment and observation, apart from mere philosophical speculation, are those of Needham and Buffon, published in 1748. Needham's theory was that vitality is produced by a force setting particles in motion, which he calls *force végétatrice*. Needham was opposed by Spallanzani, in 1777, who repeated his experiments by methods so precise as to overthrow the convictions based on Needham's labors. Schultz made an important advance by boiling his infusions and using pure air, and was followed by Schwann, Schroeder and Von Dusch. In 1859, Pouchet, one of the most ardent supporters of spontaneous generation, published his work. He does not look on these organisms as originating from dead matter, though he believes that it is the contact of different bodies which gives rise to the development of protoorganisms. Yet their origin is not due to affinity alone; vital force must also come into play, which owes its power to certain unknown concomitant circumstances. The essentials for the production of the new forms are, a putrescible body, water, and air, while heat, light, and electricity favor the process. His experiments were performed very loosely, and are subject to many errors.

Appearing shortly after Pouchet's work and leading to diametrically opposite conclusions, were the researches of M. Pasteur, who begins by attempting to demonstrate the existence of spores in the atmosphere. The greatest blow was given to the views of the heterogenists when Pasteur demonstrated that albuminoid materials are not necessary for the development of bacteria and fungi, but that they can be replaced by crystalline salts, such as phosphates and the salts of ammonia.

The experiments of Prof. Jeffreys Wyman have been largely quoted by the supporters of heterogenesis as proving their view, though Wyman himself expressed no such opinion, having approached the subject with a perfectly unbiased mind. To Prof. Wyman is ascribed great credit by Cheyne, whose results agree with his own.

Dr. Bastian (1872) gives up the theory that organic molecules are derived from previously living molecules and attempts to demonstrate that vital force and living matter may arise *de novo* under the action of the ordinary physical forces—heat, light, and electricity. This change of front on the part of the heterogenists is clearly brought about by the overwhelming evidence produced against Pouchet's views, and more especially by Pasteur's success in cultivating organisms from dust in fluids containing no organic matter.

The limitation of cases of spontaneous generation which has been gradually taking place is very instructive. Beginning with the higher

animals it became more limited, frogs, flies, etc., being by degrees excluded, till now it is only in the case of the lowest forms of life that the doctrine is asserted, and even then only in certain cases.

Not long since the people of Boston were invited to listen to a series of lectures which continues the discussion of the much-disputed question of the origin of life. The lecturer, although announcing himself as a decided opponent of the germ theory, could not agree with the spontaneous-generationists, and offered views somewhat peculiar to himself. His objective point was the so-called "*ambient organic matter*," of which he could give no definition, but in a long series of illustrations of what he meant, he showed it to be synonymous with the *bioplasm* of Dr. Lionel Beale. The term *bioplasm*, as Dr. Beale says, involves no theory as regards the nature or origin of the matter. It simply distinguishes it as *living*, e. g., a living white blood corpuscle is a mass of *bioplasm*, or it might have been termed a *bioplast*; a very minute living particle is a *bioplast*, and we may speak of living matter as *bioplasmic substance*. It is *bioplasm*, or *ambient organic matter*, according to the new view, that is at the bottom of all the functions of life, it having, to a certain extent, a low degree of inherent vitality; and the results of the various experiments that have been performed are due to the *ambient organic matter*, which has never yet been separated, it was urged, from the germs.

It was argued that the germ theorists can prove nothing till they can isolate an organism on a needle-point and use it for inoculation, after thoroughly washing and drying. Floating dust of the air, he added, is not germs, but *ambient organic matter*. He also expressed a desire to introduce some *ambient organic living matter* into the infusions and see what it would do.

Hearing it so strongly urged that we have been mistaken concerning the action and importance of the minute organisms which have made up what they lack in size by the interest they have awakened during the last quarter of a century, it occurred to me that such a theory would be of more value if accompanied by facts based upon actual experiments, but no such experiments were offered to prove the theory, which was allowed to stand by itself. In these days a theory is accepted for what it is worth, and when it relates to science it must be supported by facts. Not considering this theory capable of self-support, and not content to leave the subject in this way, I have still further investigated it.

I am reminded of Prof. Tyndall's experiments with hermetically sealed tubes. One hundred and thirty tubes were used, and to multiply the chances of spontaneous generation they were filled with infusions of the most diverse materials (in all numbering twenty-four). Each tube con-

tained an ounce of liquid and was boiled for three minutes in an oil-bath, and sealed by a spirit lamp during ebullition. Two months later this group of flasks was submitted to the inspection of the Royal Society and not one of them was found to contain life. That the infusions were not degraded by boiling was proved by similar exposed tubes which "resolved themselves with the usual speed into bacterial swarms." Special care had been taken that the temperature to which the flasks were exposed should include those previously alleged to be efficient. The conditions laid down by the heterogenist were accurately copied, but there was no corroboration of his results.

Again, sixty flasks were thus prepared containing strong infusions of beef, mutton, turnip, and cucumbers, carefully packed in sawdust and carried to the Alps, 7000 feet above sea level. Fifty arrived safely, of which twenty-three were opened on a hay-loft, and the other twenty-seven, 200 feet higher, on a ledge overlooking the Aletsch glacier. The fifty flasks, with necks open, were then placed over the kitchen stove at a temperature of 50° to 90° F. In three days twenty-one of the twenty-three opened in the hay-loft were invaded with organisms; but after three weeks' exposure not one of the twenty-seven opened in the free air had become contaminated. No germ from the kitchen air had ascended the narrow necks, the flasks being shaped so as to avoid this contingency.

Sir Joseph Lister's experiments with milk prove a great deal against the view of spontaneous generation. In his attempts to obtain pure unboiled milk, he found that in none of his flasks did he obtain lactic fermentation, but that in all but two (out of some fifty or sixty flasks), organisms of some form or other occurred, these organisms being in many flasks of totally distinct kinds. The fact that no organisms appeared in two flasks, and the great variety developed, prove that they could not have been developed *de novo*; for all being made under the same conditions any change occurring in one due to something inherent in the milk, or due to some physical force acting on it, would have occurred equally in all.

We have then a great number of experiments made by distinguished observers, of which I have quoted only a few, which show that life does not commence in substances unless something living exists in or has access to them. No one will deny the existence of the bioplasmic or ambient organic matter, but I must believe that it plays a far different rôle than was ascribed to it by the lecturer, and I also believe that the *germs* exist and play their part.

If we examine fresh blood serum, the aqueous humor of the eye, white of egg, or milk, we will find, with high powers of the microscope (1000 x),

in greater or less quantity masses of varying size and shape, made up of minute, shining, highly-refractive particles, with or without Brownian motion, which have a low degree of inherent vitality, and which are bioplasmic or ambient organic matter. No one with any experience is likely to mistake these for the minute, highly-refractive bodies of uniform size, single or in groups, which we recognize as micrococci or bacteria.

These substances, then, containing the ambient organic matter in sufficient quantity, and being free from germs, were selected for testing in the experiments which I made to see if the extraordinary statements of the lecturer had a basis of fact.

Fresh blood was caught in flasks at the abattoir, as it flowed from the necks of the animals, and was sealed up until the clot had separated. Bulbs (see tables) similar to those mentioned above, sterilized by heat, were then filled with the serum, and to the culture bulbs containing sterilized nutrient fluid, serum was added in varying quantity, and the bulbs were hermetically sealed. Milk was carefully drawn from the cow into a flask sterilized by heat, from which culture bulbs were inoculated. Bulbs were filled and culture bulbs inoculated from the white of an egg still warm from the nest, and also the aqueous humor of the eyes of freshly-killed sheep. The substances introduced into the bulbs were never boiled, because it was argued that the boiling of the infusions is unfair, by rendering them sterilized, barren, and almost inorganic.

These bulbs were kept at a temperature of about 70° F., and examined with the microscope after varying intervals. Of the forty-five bulbs (see tables), forty-four remained perfectly clear and pellucid, and the microscope revealed the same bioplasmic masses as the fresh materials. In only one were there any signs of life, and this a bulb that had been inoculated with serum, was found to be undergoing fermentation, and was swarming with the germs of putrefaction, bacteria termo, proving it to have been accidentally contaminated.

In the control experiments these materials, *exposed to the air*, under the same conditions, give a far different history, as they rapidly underwent fermentation, and then contained, in addition to the same bioplasmic masses, the germs of putrefaction. Such, then, is the effect of bioplasmic or ambient organic matter, *plus* the germs, at a temperature of 70° F. Alone, however, although upon the germinal qualities of it so much has been suggested, not only does it fail to generate life, but it has no power of reproduction, and is at best an organic nutrient material, serving the highest purpose for bioplasmic use, but having in itself absolutely no independent power of growth.

3. The same symptoms; chills, vomiting, rapid rise of temperature, etc., with the same general symptoms of a sudden intoxication.

5. The inability, in a great many cases, of the physician to say whether he has to do with lymphangitis or with erysipelas, or with a combination of both, as the disease begins sometimes in one form, sometimes in the other.

To these numerous and powerful arguments Messrs. Verneuil and Clado add another which, based upon microscopical observation, is absolutely decisive: the discovery in lymphangitis of the erysipelas microbe. This discovery, in the cases which the authors observed, combined with the results of the pure cultures and inoculations made by them, led them to the following conclusions:

1. Erysipelas and lymphangitis are simply different forms of the same contagious, infectious, parasitic disease.

2. Their agent is a special microbe which may be easily recognized, isolated, cultivated and inoculated upon animals.

3. This microbe, which had been discovered and described in erysipelas only, is also found in acute lymphangitis with all its proper qualities and characteristics.

4. It establishes, therefore, the absolute identity of two affections which, by numerous authors, have been considered so far as different diseases. —*La Semaine Médicale*, 1889, No. 16.

MEDICAL PROGRESS.

ON THE IDENTITY OF ERYSIPELAS AND ACUTE LYMPHANGITIS. — VERNEUIL and CLADO, after many microscopical experiments, say on this subject: Erysipelas and acute lymphangitis are two affections, closely related to each other, which are best and most frequently observed on the surface of the body, the nature and relations of which have often been discussed without all perfectly agreeing on these points. Some consider them one and the same disease, or at the most two forms of the same disease; others separate them entirely, although admitting that they may exist at the same time and become one.

Those taking the former view (among whom are Verneuil and Clado) advance the following arguments:

1. They have the same anatomical seat in common; lymphangitis occupies the trunk, and erysipelas the branches of the lymphatic system; both invade the ganglions.

2. The similarity in the pathological process; the two affections present, wherever they are visible, the principal symptoms of a true inflammation.

3. The same starting-point in an interruption of the continuity of the skin surface,

PAGET'S DISEASE OF THE NIPPLE.—DR. J. DARIER declares that follicular psorospermiosis is not the only affection of the skin caused by parasites of the class sporozoe. Another, which differs from the first named and is caused by another kind of psorospermæ, is Paget's disease of the nipple. In 1874 Paget called attention to a chronic affection, apparently eczematous, of the skin of the mamma and aureola, which is almost always followed by cancer of the breast: The numerous authors who have since published such cases, enumerate as characteristics of the eruption which distinguish it from common eczema: its limitation by a well defined line, the parched induration of the skin, the absolute incurability, and finally and especially the complication, after a shorter or longer period, by a cancer. Histological examinations by Bultin, Fhlin, Duhring and others did not explain the nature of the affection, which some have since regarded as an eczema which extended to the milk channels, and others as an unknown disease *sui generis*. Darier thinks that the following facts will render it possible to understand the peculiarities as yet unexplained of this type of disease.

If some of the scales are taken from the diseased surface and dissolved in water or in a solution of iodide, whether directly or after maceration in diluted ammonia or bichromate of ammonia, small round bodies, surrounded by a refracting

membrane with double contour, are at once discovered among the epithelium cells and often in their interior. These bodies have a diameter which is larger than that of the cells or equally large; their membranes contain a mass of protoplasm or of more or less numerous corpuscles. These bodies are always found in sections or fragments of the excised skin, in all the layers of the epidermis, and especially in the glandular prolongations of the epidermis. The character of these bodies admits the conclusion that we have to do with psorospermæ or coccidix. They are present in all stages of evolution; a mass of protoplasm, at first naked, subsequently surrounded by a membrane, divides itself later on into numerous granules enclosed in a cyst.

The epithelioma of the mamma contains similar parasites, and also a large number of elements which cannot with certainty be distinguished from epithelial cells, but which are often enclosed in other cells. Bultin, who saw this in 1876, thought it an instance of endogenesis. The parasites are probably more numerous than they appear to be. That they play a part in the formation of the tumor seems probable, since there is in each lobe a certain number of coccidix in their characteristic form.

It is a well-known fact that the presence of these organisms in the tissue of the epithelium produces a budding and extension of it; it is known from the psorospermosis of the gall ducts of the rabbit, and Darier demonstrated it in the follicular psorospermosis in man. Mr. Albarran quite recently exhibited epithelioma containing coccidix, and further demonstrations of this kind will soon be quite numerous. It is, therefore, logical to suppose that the parasites which produce the epidermic lesion in Paget's disease of the nipples, cause also the epithelial growth of the milk channels which constitutes the epithelioma.

The above facts appear important from different standpoints. Paget's disease of the nipple is a parasitical affection, a psorospermosis; its diagnosis becomes easy by microscopical examination of scales such as Darier made in four cases. Then also, this disease furnishes a first indication of the nature and the pathogeny of certain epitheliomas. —*La Semaine Médicale*, 1889, No. 16.

DURATION OF VITALITY OF TYPHUS AND CHOLERA BACILLI IN THE FÆCES.—PROFESSOR DR. J. UFFELMANN, of Rostock, on the basis of experiments tending to solve this question, which largely agree with those made by Kitasato, has come to the following conclusions:

In human feces, that is in human feces and urine, the cholera bacillus retains its vitality for four days at the utmost, if these feces are kept, as usual, in privies or in large kegs or tubs. As a rule it dies much sooner, generally with the second or third day, often even on the first day.

It seems to retain its vitality longer in a mixture kept at a temperature of more than 16° than in feces kept at a lower temperature than 9°. It can also be found for a longer time in those feces to which it was added in large numbers, than in those which contained but few. Whether the addition of urine hastens the end of the bacillus the author is not able to say. But the fact is of importance that it retains its vitality for at least twenty-four hours.

As regards the typhus bacillus, it was found to possess great power of resistance. Under certain conditions it retains its vitality for four months; it may even be assumed that it may last much longer, even since it existed in certain samples in large numbers at the expiration of that period. But its vitality in the feces is not always the same; different temperature seemed to have a decided effect, experiments showing that in feces kept at a temperature of 17°, or more, the bacilli increased in number, whereas with a temperature of less than 10° an increase is not to be thought of.—*Centralblatt für Bakteriologie und Parasitenkunde*, 1889, No. 16.

MENTHOL IN ASTHMA.—DR. TH. JORES, of Kastellaun, had been treating since October, 1888, a lady 50 years old who had had, in the summer of 1888, several large polypous growths removed from her nose by a specialist. When Jores took charge of the patient her principal trouble consisted in periodically (every two or three days) occurring congestions to the head, combined with difficulty in breathing. Hand- and foot-baths, purging, applications of several leeches to both sides of the proc. mastoid. gave no relief.

Gradually the congestion subsided, whilst the difficulty in breathing increased. Against these attacks, which were purely asthmatic, Jores used in the course of treatment a long series of drugs, all of which, however, were effective for a few days only. A communication in the *Allgemeinen Medicinischen Central-Zeitung* which he saw in December, regarding the favorable effect of menthol in lung disease (which effect was said to be especially on the secretion of mucus), induced him to use menthol. Whilst before the use of the drug (a 20 per cent. solution of menthol in ol. oliv.) auscultation of the lungs showed everywhere crackling and rattling noises, the trouble completely disappeared as by magic after a few inhalations; auscultation showed perfectly normal breathing, heart-beat unchanged, pulse full and strong. Patient, on being asked, simply remarked that her head felt sometimes benumbed, "as though she had inhaled chloroform without taking enough of it." Since its first application (January 2, 1889), the drug has proven effective in every attack, always with prompt success.—*Therapeutische Monatshefte*, 1889, No. 4.

CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, MAY 25, 1889.

A BRIEF REVIEW.

The records of the Association for forty years are nearly written. At Newport, on the 25th of June next, its Fortieth Annual Meeting will be convened. A few words with reference to its history and purposes will be of interest to those who, during later years, have become members of the Association.

In 1845 the New York State Medical Society, by resolution, "recommended a *National Convention of Delegates*, from medical societies and colleges in the whole *Union*, to convene in the City of New York, on the first Tuesday in May, 1846," and in the preamble set forth the objects of the meeting. In answer to that recommendation a National Convention of Delegates from medical societies and colleges assembled in the City of New York, May 5, 1846, and Dr. Jonathan Knight, of New Haven, Conn., was made chairman. Sixteen of the United States were ably represented in this Convention. A series of important resolutions was introduced, and after full consideration it was determined to refer them to special committees, who should report upon them at a second Convention to be held at Philadelphia during the following year.

On May 5, 1847, this second Convention assembled in Philadelphia, and Dr. Knight, of Connecticut, was continued chairman. The Convention was largely attended by delegates from nearly every State and Territory, and continued in session for three days. The various committees presented a series of able reports upon the resolutions

which had been referred to them severally at the previous meetings. These reports were fully discussed and, with such modifications as were deemed judicious, were adopted.

At the evening session of the third day of the Convention, May 7, 1847, it was unanimously "Resolved, That this Convention do now resolve itself into THE AMERICAN MEDICAL ASSOCIATION, and that the officers of the Convention continue to act as officers of the Association, until others are appointed."

A committee representing twenty-one States and the District of Columbia was appointed to nominate permanent officers for the Association. Nathaniel Chapman, of Philadelphia, was the first President elected. All the various officers were appointed, the committees were named, the business of the Association completed, and the Association adjourned to hold its first annual meeting in Baltimore in May, 1848.

The subsequent places of meeting and the Presidents in order have been as follows:

- 1848. Baltimore, A. H. Stevens, New York.
- 1849. Boston, J. C. Warren, Massachusetts.
- 1850. Cincinnati, R. D. Mussey, Ohio.
- 1851. Charleston, James Moultrie, South Carolina.
- 1852. Richmond, B. R. Wellford, Virginia.
- 1853. New York, J. Knight, Connecticut.
- 1854. St. Louis, C. A. Pope, Missouri.
- 1855. Philadelphia, Geo. B. Wood, Pennsylvania.
- 1856. Detroit, Zina Pitcher, Michigan.
- 1857. Nashville, Paul F. Eve, Tennessee.
- 1858. Washington, H. Lindsley, District of Columbia.
- 1859. Louisville, Henry Miller, Kentucky.
- 1860. New Haven, Eli Ives, Connecticut.
- 1861. No meeting.
- 1862. No meeting.
- 1863. Chicago, Alden March, New York.
- 1864. New York, N. S. Davis, Illinois.
- 1865. Boston, Constitution amended. Same officers continued.
- 1866. Baltimore, D. H. Storer, Massachusetts.
- 1867. Cincinnati, H. F. Askew, Delaware.
- 1868. Washington, S. D. Gross, Pennsylvania.
- 1869. New Orleans, W. O. Baldwin, Alabama.
- 1870. Washington, Geo. Mendenhall, Ohio.
- 1871. San Francisco, Alfred Stillé, Pennsylvania.
- 1872. Philadelphia, D. W. Yandell, Kentucky.

These annual meetings have been largely attended by prominent medical men representing every section of the United States. The division of the members into Sections for the purpose of special work was early found to be a necessity. The mornings are given to matters requiring consideration in general session; the afternoons to Section work. Thus ample provision is made for the presentation of papers, and for discussion in each of the special departments. The interests of the profession at large, as well as of writers themselves, cannot be better served than by giving to these several Sections the cordial support and the best service that the profession can command. Every provision for the presentation of papers in the different departments of medicine and surgery, and for their full discussion, is as ample here as can be made for special sessions elsewhere.

Among the many important and valuable results which the Association has labored to accomplish we may name:

First. By the early adoption of a Code of Ethics which commends itself to the approval of all medical men, it has clearly defined the rules that should govern, not only among members of the profession, one with another, but also their relations with the people.

Second. It has fostered fraternal fellowship, and helped to bring into close and friendly relation the medical men of all parts of this broad Union.

Third. It has always been the earnest advocate of a higher standard of medical education and in every way possible has sought to stimulate original investigation.

Fourth. Its influence has always been helpful to our medical colleges—and it has favored the maintenance of medical societies, both State and local, everywhere.

Fifth. For the purpose of assuring the closest possible relations with the masses of the profession—it even commits its own management to their delegates, as they shall come fresh from the local societies to express their will, from year to

year, rather than to permanent members, who might in time misrepresent their constituencies.

The Association is in accord with the genius of American institutions. It is National in its representation, and never sectional in interests. It is in no sense exclusive, and yet makes ample provision, for those who by reason of talent and culture, may best serve the profession as instructors and guides. More than at any previous time it commends itself to the cordial support of the profession, and it is to be hoped that it will continue to command the services of the ablest men in the profession for the furtherance of the interests of Medicine in America.

THE LICENSE TO PRACTICE.

In THE JOURNAL of May 11th, was given the able address on this subject, delivered to the Medico-Chirurgical Faculty of Maryland recently, by PROFESSOR WILLIAM OSLER. It contained a fair exposition of the evils that have resulted from leaving the whole control of medical education in this country to a large number of Medical Colleges, subject to no uniform regulations, but each authorized to grant the degree of Doctor of Medicine on such terms as its Faculty might deem proper, and yet, until quite recently, such degree or diploma was a sufficient authority to practice medicine and surgery in all the States.

The author of the address correctly states that, "the *right* to regulate the practice of medicine rests with the State." And he might have added, that the highest judicial tribunal known in this country has recently decided "that this right comes within that general *police power* which extends protection to the life and limb of the citizen." We are pleased to find him clearly and unreservedly advocating the establishment in each State of a competent tribunal, or examining board, to *examine* all candidates for license to practice, without regard to college diplomas. Whether such Board of Medical Examiners are appointed by the Governor, with the approval of the Senate, or by direct election by members of the medical profession, allowing every person legally authorized to practice, to cast a vote, we think of far less importance than the terms of the law by which the Board shall be guided in the discharge of its duties. No State Board of Examiners, however appointed, will succeed in effectually pro-

protecting the people from the depredations of ignorance and imposition, unless the law explicitly defines the minimum standard of general education necessary to qualify one to enter upon the study of medicine: and the minimum standard of medical acquirements, both theoretical and practical, necessary for safely entering upon direct practice. With these standards well defined, the State Board becomes an executive body for efficiently and impartially enforcing compliance with the provisions of the law. The law itself should state the minimum length of time each person should devote to the study of medicine, embracing all its departments, and how much of that time should be in direct attendance on medical college, practical laboratory and hospital clinical work.

The powers and duties of a Board of Medical Examiners should be purely executive and not legislative. The only legitimate object for which legislative interference with medical education and practice can be justified, being to secure for the people an educated and competent body of medical men, it is plain that the law must provide but one standard of qualifications and one uniform system of examinations for all. We cannot agree with Professor Osler, and many others, that the important department of materia medica and therapeutics might be either omitted from the examinations, or the applicant for license be permitted to choose which so-called system of therapeutics he will be examined in. On the contrary, every applicant should be examined and required to furnish evidence of having a fair knowledge of all systems. No student of regular medicine should be licensed to practice unless he also understands clearly the distinctive facts and principles of homeopathy, eclecticism, and every other medical *ism* that he is to come in contact with among the people. And no student of any one of these pathys or isms should receive a license to practice unless he is also possessed of a good knowledge of regular therapeutics as practiced by more than nine-tenths of the medical men of Europe and America. How else can any young man or woman, proposing to enter upon the practice of medicine, possibly judge what remedies and what principles guiding their application, are best and most efficient in relieving human suffering, if they have studied less than half the field, and even that under strong partisan bias? If the State undertakes to secure for the people an educated

medical profession, its laws should define clearly the standard of education required for all, and provide an efficient and impartial Board of Examiners to enforce it alike on all applicants. Then every person having passed the ordeal satisfactorily, must be allowed to exercise the most perfect right of private or individual judgment in the application of his knowledge in the practice of any or all departments of his profession.

GOOD SENSE AND CORRECT LAW.

The New York Medical Times recently proposed the following question to HON. GEO. E. BARRETT, Judge of the Supreme Court of New York: "Has a physician designating himself a 'homeopathist,' and called as such to a patient, any legal or moral right to adopt any other than homeopathic means in the treatment of the case?" To which the judge gives the following unequivocal answer:

"If," he says, "I call in a medical man who designates himself as a 'homeopathic physician,' it is because I do not wish to be treated otherwise than homeopathically. There is an implied understanding between myself and the homeopathist that I shall receive the treatment, which, by tradition and a general consensus of opinion, means small doses of single drugs administered upon the principle of *Similia similibus curantur*. If there be any variation from that method, I have a right to be informed of it, and to be given an opportunity to decide. Common honesty demands that before a confiding patient is drugged with quinine, iron and other medicaments, either single or in combination, he should be told that the 'homeopathist' has failed, and that relief can only be afforded by a change of system. An honest 'homeopathist,' who has not succeeded, after doing his best with appropriate remedies administered on homeopathic principles, should undoubtedly try anything else which he believes may relieve or save his patient. But when he reaches that point the duty becomes imperative of taking his patient into his confidence. The patient may accept the services of the homeopathist, or he may prefer another physician.

"All this is the logical sequence of a man calling himself 'homeopathist.' If I call in a man who is known simply as a physician, then I expect him to employ any or all means he may deem

necessary for my relief. With such an expectation I called for his aid. Hence, if we are to have a class of men who propose in the interest of humanity to utilize the best that they can find in any or every school, 'pathist,' as a designation of fixed methods of practice, must be ignored, and the broad and noble title 'physician,' in its unreserved sense, be revived and substituted. When a patient sends for a physician of this class, he will understand that he is to have the physician's best judgment in the unprejudiced use of the ripest fruits of modern discovery in every field."

How much longer will it require to enable law makers and the people generally to see the folly and absurd exclusiveness of the special designations assumed by persons claiming to practice medicine?

SOCIETY PROCEEDINGS.

Medical Society of the District of Columbia.

Stated Meeting, January 23, 1889.

THE PRESIDENT, CHARLES E. HAGNER, M.D.,
IN THE CHAIR.

DR. GEORGE N. ACKER presented

TWO CASES OF TUBERCULAR PERITONITIS, WITH SPECIMENS.

Case 1.—Joseph Brown, æt. 4, colored. Residence 427 O street, alley. Father and mother both living and apparently healthy. Child was perfectly healthy up to six months ago, when he was taken with measles, which left him weak and with a cough. Three days ago was taken with diarrhoea, from three to six movements daily, for which he was admitted to the hospital August 22, 1888.

Present condition.—General appearance much emaciated, abdomen pendulous. Temp. 99.5°. Has a dry hacking cough, with fine moist râles over both lungs anteriorly and over left lung posteriorly. Respiration 30. Tongue coated white, thirst, anorexia, pain in epigastric region, diarrhoea, one to four movements daily, character of stools yellow with white flakes. Abdomen very tympanitic.

August 24, temp. subnormal (96.5°-97°), perspires profusely, one movement of bowels in last twenty-four hours.

August 26, temp. still subnormal, three dark watery stools.

August 28, stools formed, no diarrhoea. Temp. subnormal.

August 30, general condition better.

September 5, gradually improving. Evening temp. 99.1°; morning 97.4°.

September 10, from one to two passages of bowels in twenty-four hours. Temp. again subnormal. General condition much better, allowed to sit up.

September 20, general condition much better, allowed to get up and go about the ward. Temp. about normal.

October 1, apparently well except the distended abdomen.

October 15, boy has some cough but allowed to go about the ward.

October 26, cough continues. Physical examination shows dulness at left apex ant. Broncho-vesicular breathing with fine moist râles over left apex ant. Patient put to bed.

November 1, temp. a little above normal.

November 7, patient is becoming emaciated, cough somewhat exaggerated, perspires profusely at night, abdomen much distended.

November 17, since the 7th has had from one to four passages from the bowels in twenty-four hours. Temp. ranges from normal in the morning to 102° in the evening.

November 20, evening temp. 102.5 to 103°.

November 24, abdomen enormously distended.

November 28, patient is gradually growing weaker. No treatment seems to relieve the tympanitic condition of abdomen. Very restless at night.

November 30, temp. ranges from 99°-100°. No apparent change in condition. Has from four to five stools daily.

December 3, a consultation was held, when the following physicians were present: Drs. Lovejoy, King and Dr. Acker, including the attending surgeon, Dr. Thompson. A laparotomy was suggested, but as no fluid could be detected in the peritoneal cavity Dr. Thompson thought an operation would be useless.

December 10, no apparent change except more emaciated.

December 20, temp. normal, patient very weak.

December 27, evening temp. 101.4°; morning 101°.

December 29, abdomen considerably reduced in size.

January 1, 1889, died 10:15 A. M., from exhaustion.

Necropsy held twenty-four hours after death; rigor mortis slight, general appearance much emaciated, enlarged lymphatic gland left groin. On opening the chest numerous adhesions were found in left pleura, due to the deposit of tubercle. The left upper lobe was thickly studded with tubercular masses, lower lobe presented decided thickening of the walls of the bronchial tubes, probably due to free-bronchitis. Over anterior surface of left lung small portions were

found to be in a condition of atelectasis. Right lung normal except in a state of passive hyperæmia. Diaphragm and capsule glisson were the seat of caseous masses about one-fourth of an inch in diameter. In the umbilical region the paired layer of peritoneum was firmly attached to the mesentery by numerous adhesions, and could only be separated with considerable force. No fluid was found in the peritoneal cavity. Spleen slightly enlarged. Other organs normal.

Case 2.—Ida Samson, æt. 2, colored. One year ago was taken with pneumonia, which left her with a bad cough, which has continued up to the time of her admission to the hospital, November 19, 1888.

Present condition:—General appearance fairly well nourished. Temp. 100.5°. Has a paroxysmal cough, no expectoration, rapid breathing, small and large râles over both lungs anteriorly.

December 1, physical examination shows marked dulness over apex of left lung, also bronchial breathing. Cough continues about the same.

December 17, face and hands very œdematous. Perspires profusely.

December 24, swelling has nearly disappeared from face and hands.

December 28, gradually growing weaker.

January 4, died from exhaustion.

Necropsy held twenty-four hours after death: rigor mortis slight, body much emaciated. On opening thorax numerous adhesions were found on left side. The upper lobe of left lung was found entirely consolidated, small emphysematous spots were found on lower lobe, left side. A few miliary tubercles were found over surface of left lung, pleura and diaphragm. On opening the peritoneal cavity about six ounces of fluid escaped. Several large caseous masses were found in the mesentery the size of a large hickory nut. About these masses the mesentery was found to be deeply injected. Other organs normal.

DR. J. FORD THOMPSON: When he was first asked to see this patient, Joe Brown, he favored an operation; but the second time he examined the patient he abandoned the idea. He now based his opinion upon the fact that the child was nearly dead, and that it had a resonant and tympanic abdomen. There was no dulness and he could not detect fluid. He could not see what an operation would accomplish. Dr. Acker favored an operation. He had never seen such an extensive tubercular disease in the abdomen; the intestines were adherent as one mass, and there was not a spot that he could find to contain the fluid that was supposed to have been in the abdominal cavity. From the enlarge mesenteric glands and the enormous deposits in the mesentery he unhesitatingly called it *tabes mesenterica*. What could an operation have accomplished in such a case? The intestines were so adherent

that Dr. Dillenbach tore them in getting them out. The absence of fluid in the abdominal cavity proved this to be an exceptional case. Dr. Acker reports a case which is wholly unlike this, in which the surgeon operated for a cystic tumor. Any surgeon would have operated in that case. Had he operated in Dr. Acker's case he would have had the credit of killing the child.

DR. ACKER: The glands were not enlarged as much as we usually find in *tabes mesenterica*. It was undoubtedly tubercular enlargement. Dr. Thompson had contended that the mesenteric glands were greatly enlarged, but Dr. Lamb had confirmed his (Dr. A.'s) statement that they were only enlarged about as much as is usually found in tuberculosis. Dr. Thompson had seen this patient a month and a half before she died, and it was then that Dr. Acker thought that he detected fluid in the peritoneal cavity. He now believed that this fluid had been absorbed and passed by the numerous stools which she had been having daily for sometime prior to death. If the child had been operated on about December 15, when it was first seen by the consulting staff, some good might have been accomplished. The cases reported had been benefited by laparotomy.

DR. THOMPSON: Dr. Lamb's statement had surprised him very much, especially as Dr. Dillenbach had reported to him that he had torn out masses larger than walnuts. There was not a mesenteric gland in the whole specimen that was not diseased, which was apparent from microscopic examination. It would have been madness to have operated upon such a case. If he could have detected fluid he would have performed laparotomy but the abdomen was highly resonant. What would an operation have accomplished in this case?

DR. BUSEY desired to learn something more about the surgical treatment of such cases, and would therefore ask Dr. Acker to supply the clinical histories of the cases he mentioned. Had the tuberculosis invaded any other structures? In Dr. Aker's case there was also tubercular disease of one lung. Did Dr. Acker propose to operate for cure in this case? In the cases reported as operated on was there any complication, or was the tuberculosis confined to the peritoneum? Did the clinical histories of the reported cases correspond with that in Dr. Aker's case? For if simply opening the abdomen in cases of tuberculous peritonitis would cure them, it was one of the most marvelous anticipations of surgery. He could only arrive at a conclusion after knowing the clinical histories, and what was proposed by the operation. Judging from what had been said he thought it was a simple operation with a marvelous result.

DR. GEORGE WOODRUFF JOHNSTON had looked over the literature of this subject about a year ago and found 20 or 30 cases that had been oper-

ated on that were reported at the German Surgical Congress and elsewhere. There was fluid in the peritoneal cavity, sometimes encysted and sometimes free. A large per cent. were cured by the operation. That they were cases of tuberculosis was proved in many instances by the detection of the bacillus tuberculosis in excised nodes. The abdomen was drained, the wound sometimes closed and the fluid did not reaccumulate. In some drainage was the only treatment; in some the abdominal cavity was washed with a solution of salicylic acid and other antiseptics; and in still others iodoform was applied. Pulmonary lesions seemed to form no decided contra indication to the operation; in fact, after the operation the pulmonary lesion improved markedly. The operation is limited in its indications; and in certain cases it is contraindicated. Where there is fluid in the abdominal cavity the operation is indicated; and when there is no fluid present, as appears to have been the case with Dr. Acker's patient, nothing could be achieved by opening the abdomen.

DR. LAMB: In one of the specimens the glands were enlarged as much as an inch in diameter; and in the other there were tubercles and fibrous tissue.

DR. THOMPSON agreed perfectly with Dr. Johnston. There was no place for fluid in this patient's abdominal cavity. The operation may be justifiable in some cases and not in many others.

DR. ACKER: The tubercular process was limited to the left lung of this patient.

DR. M. F. CUTHBERT presented for Dr. J. Taber Johnson:

I. VAGINAL HYSTERECTOMY: NOTES OF A SUCCESSFUL CASE.

2. OVARIAN TUMOR: NOTES OF THE CASE.

Mrs. B., white, æt. 53, mother of five children, all living, had been treated for cancer of the uterus for several weeks by Dr. N. S. Lincoln. Dr. L. referred her to me for operation the last week in November, 1888. As there was no odor to the discharge I consented to receive her in my private hospital, and at once operated for the removal of the entire uterus.

The operation was difficult on account of the almost complete destruction of the intravaginal portion of the cervix. When the vulsellum was applied it would tear out of the friable cervical tissues, making the separation of the bladder and rectum very tedious. The main point of interest in the operation was the use of the pressure forceps to control hæmorrhage instead of ligatures, as recommended by Péan, of Paris, Dudley, of Chicago, and others. The use of Keith's long-bladed and long-handled forceps made it unnecessary to use more than one pair on each side of the uterus. Dudley, in his recent paper, states

that, in one operation, as many as seventeen pairs of small pressure forceps were left dangling from as many bleeding points.

Wathen, of Kentucky, recently reported a case to the Southern Gynecological Society in which he operated successfully, there being about twenty forceps applied to bleeding points and protruding from the vagina. Some operators remove the forceps in twenty-four hours, while others leave them on three days. I left mine on as long as precedent permitted, and finally removed them on the third day with some fear and trembling lest uncontrollable hæmorrhage should follow. None occurred, and the patient made an uneventful recovery and left the hospital for home on Christmas day, just three weeks from her operation.

She had no shock following the removal of her uterus, and her speedy convalescence was marked by less trouble than frequently follows Emmet's operation for a lacerated cervix. She has since continued well except some irritation of the bladder which troubles her principally when she stands or walks too much, when she feels "a drawing or pulling sensation, as if something had healed crooked," as she says. I presume the bladder misses some of its support when she stands erect. I used no sutures in any of the tissues, and no dressing except a little iodoform gauze in between the forceps in the vagina. I have now done this operation four times, with two deaths and two recoveries.

One advantage claimed by Reamy and others for the use of the pressure forceps over the ligature in this operation is, that the tissues grasped by their blades, as well as that above them, all sloughs away, thus destroying more tissue than the ligature, and rendering the return of the disease less liable to occur on this account. They are much more easily and quickly applied than ligatures, and at the same time ensure better drainage; and as time and drainage are important factors in vaginal hysterectomy, the use of the pressure forceps would seem to be an important improvement in this difficult and dangerous operation.

Mrs. S., white, German, æt. 42, the mother of five living children, was referred to me by my friend, Dr. C. H. A. Kleinschmidt, about a month ago. She had been well up to September last, when, in an ocean voyage across the Atlantic, she was made conscious of a sore lump in the right side of her abdomen. She thought that excessive seasickness had made her sore and lame.

This condition of things continued after her arrival in this city, and she consulted Dr. Kleinschmidt, who, upon examination, discovered a tumor which he diagnosed as ovarian. Its rapid growth and the pain attending it caused him to fear malignancy. When I saw it I agreed with his diagnosis and shared his fears that it might already be undergoing cancerous degeneration.

and recommended an immediate operation as the only mode of saving her life.

In the course of the succeeding month, while the family were coming to a conclusion and making the necessary arrangements for an operation, it greatly increased in size, and on account of her pain and other symptoms she was compelled to spend much of her time in bed. She was taken to a private room in Providence Hospital on the 14th of this month, and after several days of preparatory treatment she was operated on the 19th inst., in the presence of Drs. Kleinschmidt, Cuthbert, Crook, Sellhausen, Schneider, Van Rensselaer and others. The usual incision was made, the cyst was tapped with Tait's trocar and about 10 quarts of very dark-colored fluid withdrawn. The cyst was multilocular, and before it could be withdrawn several smaller cysts were also tapped, discharging different kinds of fluid, some of it being thin, of a light straw-color, and some of it being a thick colloid material which would not flow through the trocar.

The cyst wall was so firmly attached to the omentum that a number of ligatures were required to control hæmorrhage after its separation. There was quite a firm adhesion to the parietal peritoneum on the left side, which was probably the cause of the pain from which she had suffered. The pedicle was at first clamped with three of Keith's long blade pressure forceps, and the tumor cut away from its very broad pedicle. The omentum was then drawn out upon the abdominal wall, carefully pressed with hot sponges, ligatures applied to several bleeding points, and carefully returned. The abdominal cavity was thoroughly washed out with several pitchers of filtered hot water, the pedicle was transfixed, ligated, trimmed and dropped. No further bleeding having occurred, the abdominal wound was closed in the usual way and the usual dressings applied. The fluid and solid parts of the tumor were found to weigh about 30 lbs. The other ovary, being normal, was not removed. The patient is now in the latter part of her fifth day and bids fair to make a good recovery. I should be glad if the microscopical committee would kindly examine the solid parts of the tumor and report upon the question of malignancy.

Tennessee State Medical Society.

Fifty-Sixth Annual Meeting.

FIRST DAY—MORNING SESSION.

The Tennessee State Medical Society met in its fifty-sixth annual session in the Senate Chamber of the State Capitol on Tuesday, April 30th ult., with the largest attendance that it has ever had during its existence, no less than 185 members

being in attendance. All parts of the State, the eastern, western and middle divisions were ably represented by earnest, able and progressive members of the profession.

The Society was called to order at 10:30 o'clock by the President, Dr. T. J. Happel, of Trenton. Secretary, Dr. D. E. Nelson, of Chattanooga, and Treasurer, Dr. Richard Cheatham, of Nashville, were in their places. Drs. Charles M. Drake of Knoxville, and C. W. Beaumont, of Clarksville, Vice-Presidents for East and Middle Tennessee respectively, were present. Dr. D. D. Saunders, of Memphis, Vice-President for the Western Division, was absent.

Prayer was given by Rev. Dr. Scroggins, of Mexico.

DR. G. C. SAVAGE, Chairman of the Committee of Arrangements, made remarks concerning railroad rates and entertainment.

A recess was taken to allow the Committee on Credentials, composed of Drs. W. T. Briggs, J. P. C. Walker and G. W. Drake, time to prepare a report.

DR. J. S. CAIN, in the absence of Chairman Saunders, of the Committee on Legislation, made a verbal report of that committee. He detailed the progress of the medical regulation bill in the Legislature, and spoke favorably of the law. He believed it could be made effective if a proper, judicious committee would watch its operations and from time to time report recommendations of changes. He submitted a resolution setting forth, that as the law, while in many respects is imperfect and objectionable, it is a step in the right direction, and if judiciously administered will result in the correction of many of the evils from which the profession and the public suffer; that in the opinion of this Association, it is a duty incumbent upon every reputable physician in the State, to lend his aid and influence to the faithful enforcement of the law, and to strive to obtain such future legislative amendments as may render the same most efficient in elevating the standard of honorable medicine in our State, and in protecting the public against the evils of ignorant quackery: further, that the Association repudiates the term *Allopath*, which by some means gained admission into the said Act as a term of contradistinction from *Homoeopath* and *Ecclectic*, respectfully declining to be side tracked with these dogmatists upon an exclusive "pathy," and re-asserting the broad dominion of regular or honorable medicine as embracing the entire field of medical agencies.

The report and resolutions were adopted.

DR. C. W. BEAUMONT, of Clarksville, said the law was now upon the statute books as a result of forty years' labor, and no matter how imperfect it might be, it should be made as effective as possible, and the way to do so was by wise and judicious administration.

He offered a resolution which provided that the President of the Society should appoint two members from each grand division of the State, who, with himself, should act as a committee, to select four members of the Medical Examining Board, and suggest the same to the Society at 11 o'clock next day, and that the Society suggest these names to the Governor for appointment.

After some further discussion the Society adjourned to 2:30 P.M.

AFTERNOON SESSION.

The Society was called to order at 2:30 o'clock and the discussion of Dr. Beaumont's resolution continued.

DR. G. W. DRAKE, of Chattanooga, moved to amend Dr. Beaumont's motion so as to provide for the nomination of three examiners instead of four.

DR. GARDNER, of Dyersburg, said the mass of the people in his section were opposed to having the State regulate medicine, and he thought the Governor should be allowed to make his own appointment without interference from the Society.

DR. DUNCAN EVE favored the acceptance of the amendment and the nomination of a committee to select three Examiners.

DR. DEERING J. ROBERTS stated that the medical regulation bill was now a law. He was a law abiding citizen of the State of Tennessee, and would endeavor to abide by its laws. While the enactment was not such as was desired by the most ardent advocates of "Protection for Medicine," it was the law of the land, and he believed that the best plan at present was to keep our hands off, and as good citizens abide by the law. It had its objectionable features, as admitted by the representative of the committee to whom was appointed the duty of looking after its enactment. It had been accepted by the Society by a vote that is now on our minutes, and it seemed to him that it was now at least, as it had ever been, incumbent on us to keep our hands off. To take any further action in regard to it, other than to obey the law as it stands may evoke a question that had best not be raised.

Drs. Lipscomb, Powell and Menees made vigorous arguments in favor of the appointments.

The motion was put and carried. Drs. Deering J. Roberts and W. F. Glenn asked leave to file their protests, which was granted.

This question being settled, the next business was a most excellent and practical paper which was read by Dr. J. E. Reeves on the *Use of the Microscope*.

DR. C. H. LOVELACE, of Dukedom, then read a paper on *Enlarged Tonsils with a Report of a Case of Excision*, which elicited quite a lengthy discussion.

The President appointed as a committee to select nominees for Medical Examiners: Drs.

Thos. Lipscomb, C. N. Cooper, G. W. Drake, T. K. Powell, J. W. Penn, C. W. Beaumont. The Society adjourned until 8 o'clock.

NIGHT SESSION.

The night session was held as a public meeting in the Theatre Vendome. A large audience, composed of members of the Society and their friends, and many ladies and gentlemen of the Capital City were present, and a pleasant occasion had.

Music was furnished by the Italian band.

The meeting was opened with prayer by Rev. Dr. Fitzgerald.

The address of welcome was delivered by Dr. G. W. F. Price, Gov. Taylor not being able to be present.

DR. T. J. HAPPEL, of Trenton, President of the Society, delivered an able address on *Alcohol as a Medicine*.

A concert under the direction of Mrs. A. H. Stewart was excellently carried out and received much applause.

SECOND DAY'S SESSION.

The Society was called to order at 9:30 by the President.

Prayer was offered by Rev. C. D. Elliott.

DR. T. J. MURRAY, of Butte, Mont., was invited to a seat in the Association.

DR. THOS. LIPSCOMB, of Shelbyville, made a report of the Committee on Necrology, giving particulars of the death of Drs. J. M. Towler, of Maury, and H. H. Clayton, of Murfreesboro. Papers concerning each were read and filed.

THE PRESIDENT named the following physicians who had died during the preceding year, and whose deaths had not been reported: Dr. H. Lane, Calhoun; H. W. Purnell, Memphis, and B. F. Lackey, Lauderdale County.

DR. D. J. ROBERTS moved that the name of the late Dr. Thomas B. Buchanan, of Arkansas, formerly of Nashville, be added to the list. Carried, and Dr. Roberts by vote of the Society was requested to prepare a memorial of Dr. Buchanan for publication in the *Transactions* of 1889.

On motion of Dr. Plunkett the Necrological Committee was increased to one member from each Congressional District.

DR. D. E. NELSON, Secretary of the Society, submitted his report, which was accepted and filed. It showed, previous to the meeting, 254 members in good standing.

DR. J. B. MURFREE, of Murfreesboro, read an able and lengthy paper on *Diseases peculiar to Gestation*.

This article excited lively discussion, which continued about two hours. Among those discussing it were Drs. O. C. Omohundro, Thos. Menees, Thos. Lipscomb, P. H. McKinney, L.

C. Chisolm, W. A. Atchison, J. W. Maddin, Sr., W. A. H. Coop, W. F. Glenn. The paper was referred to the Committee on Publication.

DR. RICHARD CHEATHAM, Treasurer, submitted his report for the past year, showing receipts amounting to \$367.67, and disbursements of \$536.35, leaving a balance of \$168.68 due the Treasurer.

The committee appointed to suggest names for recommendation to the Governor for appointment as Medical Examiners submitted its report, making the following nominations: East Tennessee, Dr. C. Deadrick, of Knoxville; Middle Tennessee, Dr. J. B. Murfree, of Murfreesboro; West Tennessee, Dr. D. D. Saunders, of Memphis, and alternate, Dr. J. W. Penn, of Humboldt. The report was adopted.

Dr. G. W. Foster, of Stevenson, Ala., was invited to a seat in the house.

On motion of Dr. W. F. Glenn, 3 o'clock was fixed as the hour of holding the annual election of officers.

The Society adjourned till 2 P.M.

AFTERNOON SESSION.

A resolution that Dr. Thos. Lipscomb be made an honorary member of the Society, and that from and after this meeting he be exempted from all dues, was carried.

DR. PAUL F. EVE, of Nashville, read a paper on *Hip-joint Amputation*, which he illustrated by a living subject, a colored man, who, on the 10th of last October, was accidentally shot in the thigh by a 42-calibre bullet, and the amputation of whose right leg at the hip had been necessitated.

DR. ROBERTS spoke of the operation as one of the comparatively few successful cases of the kind. The paper was referred to the Committee on Publication.

DR. F. M. DUKE, of Wartrace, read a paper on *Typho-Malarial Fever*.

Three o'clock having arrived, the election of officers was taken up, and the selection of a President declared in order.

The first nomination was that of Dr. Duncan Eve, by Dr. G. A. Baxter, of Chattanooga.

DR. J. B. MURFREE, in a neat address, nominated Dr. C. W. Beaumont, of Clarksville.

The ballot resulted: Eve, 79; Beaumont, 55. Dr. Eve was declared elected and was escorted to the stand by Drs. Savage and W. F. Glenn. He was introduced by Dr. Happel. He said he would not consume the time of the meeting by a speech, but he was thankful for the honor, and would be satisfied if he should make as good a President as Dr. Happel had proven. The following Vice-Presidents were elected: East Tennessee, Henry Berlin, of Chattanooga; Middle Tennessee, Jas. B. Neil, of Marshall; West Tennessee, J. P. C. Walker, of Dyersburg. The committee appointed to audit the report of the

Treasurer reported the same as correct. Drs. D. E. Nelson, of Chattanooga, and Richard Cheatham, of Nashville, were unanimously re-elected Secretary and Treasurer respectively.

After considerable discussion, Memphis was selected as the place of the next annual meeting, to be held the second Tuesday in April, 1890.

A paper on *Laparotomy in Visceral Gunshot and Incised Wounds* was read by Dr. C. S. Briggs, of Nashville. A paper on *Heterophoria* was read by Dr. G. C. Savage, of Nashville, and illustrated by a number of patients.

The Society adjourned to 8 o'clock.

NIGHT SESSION.

The Society was called to order by the President at 8 o'clock.

The Secretary read a letter from Dr. J. R. Rathmel, of Chattanooga, regretting his enforced absence, and enclosing a paper on *Tubercular Meningitis*. This paper was referred to the Committee on Publication.

A paper prepared by Dr. J. A. Cook, who was forced to leave during the afternoon, was also handed in and referred.

DR. R. F. KEYS, of Nashville, read a paper on *the Physiological Action of Alcohol*. After some discussion it was referred to the Committee on Publication.

The next paper was read by Dr. C. W. Beaumont, of Clarksville, on *Asphyxia Neonatorum*.

DR. W. F. ROCHELLE, of Jackson, read a paper on *Long Standing Uterine Displacements Incurable: What Shall We Do With Them?*

The papers read were referred to the Committee on Publication.

At 10:30 o'clock the Society adjourned to meet at 9 o'clock next morning.

THIRD DAY—MORNING SESSION.

The Association was called to order at 9:30 o'clock by President Happel.

Prayer was offered by Rev. Dr. C. H. Strickland.

DR. T. J. HAPPEL announced that he would now turn over the gavel of office to the newly elected President, Dr. Duncan Eve. He thanked the Society for its favorable treatment of him, and said that while he had labored to faithfully discharge his duties, the unprecedentedly large meeting this session was mainly due to the efforts of the Secretary, Dr. D. E. Nelson.

DR. EVE called the body to order.

DR. L. R. MOSS moved that a resolution of thanks be tendered Dr. Happel for his excellent administration as presiding officer of the Association. The motion was seconded and carried unanimously by a standing vote.

DR. J. D. PLUNKET stated that there was in the library of the State Board of Health a printed copy of the report of the proceedings of the Med-

ical Society for 1853, which he believed to be the only one published before the war now in existence. This contained a full list of members up to that date, all the other records before the war having been destroyed.

A motion that a committee of three, of whom Dr. Plunket should be Chairman, be appointed to make a synopsis of this report for publication was adopted.

A motion that the President appoint a new name in the place of any member nominated for State Medical Examiner who might resign was carried.

The thanks of the Society were returned to the Secretary and the Treasurer, and \$50 voted to the former in some recognition of his services.

DR. DEERING J. ROBERTS moved that the Society pass a resolution requesting the Legislature at its next meeting, May 7, to pass the bill providing for the registration of births, deaths and marriages. After much discussion the resolution was adopted.

A paper on *Report of Surgical Cases* prepared by W. B. Wells, of Chattanooga, who was unable to be present, was read by title and referred to the Committee on Publication.

The next paper was read by A. J. Swaney, of Gallatin, on *The Wire Corset in the Treatment of Spinal Affections*, with exhibit. It was discussed and referred to the Publication Committee.

DR. W. D. HAGGARD, of Nashville, read a report of *Four Abdominal Sections*, one of which was a successful case of hysterorrhaphy, which was discussed at length.

A paper was read by Dr. C. N. Cooper, of Cleveland, on the subject, *Report of a Case of Self-Castration and a Case of Ovariectomy with Complications*.

DR. F. T. SMITH, of Chattanooga, made an exhibit of Surgical Instruments.

A paper by Richard Douglas, on *Hysterectomy*, was read by title and referred.

DR. W. F. ROCHELLE, of Jackson, read a paper on *Gonorrhoea and its Treatment*.

DR. T. A. ATCHISON was requested to prepare for publication his remarks on *Recent Additions to Our Pharmacopoeia*.

DR. RICHARD DOUGLAS, by request, made a talk on his recent visit to Europe.

A vote of thanks was extended the Committee of Arrangements, the press, railroads and hotels.

After announcing the following committees, the President declared the Society adjourned until the next annual meeting at Memphis:

Committee to wait on the Governor to urge the appointment of the physicians nominated by the Society for the Examining Board—Drs. G. S. Glenn, J. S. Cain and J. D. Plunket.

On Credentials.—Drs. T. J. Happel, A. P. Watterfield, W. F. Crunk, G. B. Thornton, G. A. Baxter, J. D. Plunket and M. Campbell.

On Arrangements.—Dr. D. D. Saunders with power to appoint the others.

On Publication.—Drs. D. E. Nelson, D. J. Roberts, C. S. Briggs, W. M. Vertrees, P. D. Sims, J. B. W. Nowlin and J. M. Coyle.

On Necrology.—First Congressional District, Dr. N. T. Dulaney; Second, Dr. C. Deadrick; Third, Dr. P. D. Sims; Fourth, Dr. T. M. Woodson; Fifth, Dr. Thomas Lipscomb; Sixth, Dr. J. D. Plunket; Seventh, Dr. B. J. Harlan; Eighth, W. C. Crook; Ninth, Dr. T. K. Powell; Tenth, Dr. F. L. Sims.

Delegates to the American Medical Association.—Drs. G. B. Gillespie, T. K. Powell, W. H. Harris, A. P. Watterfield, Richard Douglas, W. F. Glenn, W. J. Miller, C. N. Cooper, B. B. Lenoir, W. F. Crunk, W. K. Sheddan, B. J. Harlan, J. A. Witherspoon, J. H. Tripp, W. A. H. Coop, D. E. Nelson, M. Campbell, T. J. Happel, D. C. Savage, T. R. Moss, A. J. Swaney, N. T. Dulaney, Paul F. Eve, J. Berrien Lindsley, J. W. Penn, C. W. Beaumont, D. J. Roberts, A. B. Brown, J. B. W. Nowlin, J. D. Plunket, F. M. Hughes, J. W. Maddin and F. B. Sloan.

The American Surgical Association.

Annual Meeting, held in the New Army Medical Museum, Washington, May 14, 15, and 16, 1889.

DR. DAVID W. CHEEVER, of Boston, delivered the *President's Address* on

THE FUTURE OF SURGERY WITHOUT LIMIT.

I believe that we are warranted in saying that the future of surgery is without limit. I deduce this conclusion, first, from considering what the mind of man has already done; second, from the future possibilities of fields hitherto unknown and unexplored, but now opening up to science. There can be but two limitations, either in the mind of man or in the subject.

Since the time when in the anthropoid the cerebral lobes first began to creep over and cover the cerebellum, what a growth has taken place in the penetrating power of the human senses. The brain has progressed from the rude hammer of the prognathous cave-dweller to the telescope and the microscope. Originally of vision far less acute than the eagle's, the eye of man ranges from the fixed star to the twenty-thousandth of an inch bacteria. We analyze the sun's gases with the spectrum; we follow the magnet unerringly on the sea; we utilize the lightning; we count the vibrations of sound; we measure light; we speak across the ocean; we estimate the age of our planet; we analyze atoms; we compose new substances; we make

pictures from light ; we photograph and map the stars ; we explore the pole and test the glacial history of the world ; we find subterranean springs and light our homes from old volcanic sources ; we measure the crevasses in the glaciers of Mars ; we count tides by the moon ; we defy the wind with steam ; we foretell storms by the barometer ; we construct isothermal lines ; we inspect the bottom of the sea ; we demonstrate eclipses ; we measure space by the transit of Venus ; we predict comets ; we find a solar and a stellar unit of time ; we unravel Egyptian chronology ; we trace man downward through the stages of evolution. Man invents the wheel, the ship, the pendulum, the syphon. Under the water, in and on the earth, in the air, in the infinity of space, in the infinity of microorganisms, the mind finds no limit, but is ever-restless, ever-searching. And now in medicine, averting pestilence, annulling pain, destroying sepsis, shall we stop ?

In gradual development the brain of man has gone on, step by step, investigating itself, until we localize disease by the tracings on cerebral surfaces and condense in that wonderful cortical substance a palimpsest of impressions, mental and material. The brain studies itself. Know thyself, said the Greek, and in searching the crypts of the human brain we may well echo the description of the greatest of the sons of men, "How noble in reason ! How infinite in faculties ! In apprehension, how like a God !

We pass now to the second limitation ; in the subject itself. Long since it was said that all was found out in anatomy, and that surgery had nearly reached its limit. Far from this, the microscope has created a new anatomy and a new pathology ; physiology changes yearly ; the lower animals yield light by the Baconian test of experiment. Anæsthesia enlarged surgery ; antisepsis emboldens surgery and we can set no limits to the advance.

The three secret cavities, the abdomen, which means the hidden ; the thorax, which holds two feet of the tripod of life ; the skull, which conceals the nerve force, the vital principle, all are explored.

Medicine, always obscure, is growing clearer, and instruments of precision have been applied to our art. The clinical thermometer is the tell-tale of internal changes, inflammatory or septic. What have we to fear ? We advance haltingly, but we advance.

Specialism exhausts localities ; by its occasional discoveries enlightens medicine ; by its failures calls sometimes a halt. Specialism tempered by general medicine becomes a safe companion in our march onward.

It becomes us soberly to inquire how to study the new seats of surgical exploration. What new methods are needed ? Where must we be conservative ? Where can we be bold ? Since medicine is

composed of a science and an art, we must study the science to develop the art. The four pure sciences are anatomy, physiology, chemistry, and pathology. These purely scientific portions of our profession are the only ones that can yield positive knowledge, and this only by dissections, experiments and analyses.

Modern surgery deals with anatomical regions hitherto insufficiently studied. First, the *fasciæ*, the lining and bindings of the muscles, vessels and nerves, have great influence in determining the course of suppuration and the size and locality of abscesses. A perfect dissection and preparation of the *fasciæ* does not exist. It is, perhaps, impossible to make it. Frozen sections and their photographs give the best idea of the relations of the *fasciæ*. Familiar instances of the importance of the arrangement of the *fasciæ* are to be found in the Psoas sheath, the saphenous opening, the triangular ligament of the perineum, the deep cervical fascia, the fascia lata, the fascia of the forearm and the annular ligament, the posterior ligament, or fascia of Winslow in the popliteal space.

Next, the topographical anatomy of the viscera, especially in the abdomen, not only the variations in the reflexion of the peritoneum, but the mobility of the organs ; the rhythmic changes produced by respiration on the veins, on the diaphragm as an agent of displacement, and on the pelvic diaphragm, the perineum ; the incessant movements of peristalsis its power to change the locality of organs. All these have not been sufficiently considered by the diagnostician and by the operator. Normal splanchnology and frozen sections of the abdominal cavity are of more worth to the student than the mnemonics of the origin of all the muscles and the twigs of all the arteries. The exact relations of the mediastine to the œsophagus, aorta, pericardium and pleural cavities are of great importance also.

No less directly useful is an exhaustive and minute topography of the brain, the bearings of falx tentorium, corpus colosum, ventricles, the centers of decussating fibres, the ultimate origin of the fibres of the cranial nerves, the sinuses, the relations of the middle-ear, the petrosal sinuses, the mastoid cells and their variations, the fissures of Sylvius and Rolando.

When we consider physiology we are struck both by its great progress and by its imperfections. The older physiology is obsolete and discarded, but in the newer physiology the functions of some large and important organs are still undetermined. The ductless glands, for instance, the spleen, the thyroid, the thymus, the supra-renal capsules. An ignorance of their functions renders the surgeon unable to predict the consequences of their removal. Of what avail the brilliant operation to excise a double goitre, if it is to be followed by an obscure degeneration of the nervous or glan-

dular systems? Again, in organs of known functions, the limit of the digestive power of different portions of the alimentary canal is not yet definitely learned. How can we get along without a gall-bladder? How important is the pancreas? Can the duodenum supplant the stomach in nutrition? How much ileum can be removed without starvation? What will the rectum digest? All these are pertinent questions for the physiologist, and have a direct bearing on modern surgery.

In chemistry, the whole study of sepsis, anti-sepsis, fermentation, germicides, the viability of spores, is in its infancy; and as certainly as it already has reversed surgical practice, will it do so again and again.

The great desideratum of surgery now, if chemistry can supply it, is a new, constant, local anæsthetic. This would enable us to banish a chief cause of secondary shock from our operations.

Finally, in pathology we have much to learn and to influence our surgical practice. Diseased organs change appearance and they change place. A double puzzle is thus presented to the operator. On opening the abdominal cavity we are sometimes at loss to locate an organ, and even fail to recognize it, so changed is its look and its surroundings. One part is mistaken for another, a sac for intestine, intestine for sac, adhesions for peritoneum, and so in many other instances. It is of the last importance that the operating surgeon should be so familiar with the pathological changes that he can distinguish the false from the true at a glance.

The future destiny of coarse pathological changes of organs, whether they are hopelessly diseased; whether they can recover; whether the affection is organic or inflammatory, is also to be decided, rightly or wrongly, by the surgical expert on a brief inspection.

Having considered how much we may learn or hope from the pure sciences, we pass to the other limitation of the subject, the arrest or the cure of morbid processes. All surgical disease is inflammatory or organic; we must advance by checking the inflammatory process, or by preventing morbid growths; the first, by arresting suppuration; the second, by discovering the causes of all change and cell proliferation. Through surgical pathology lies the only path. True conservative surgery would then be limited to arresting the consequence of traumatism. The earlier labors of Paget and the later ones of Virchow, Pasteur and Koch, give us some hope of being able to abort suppuration, to inoculate for tubercle, or to eliminate the cancer cell. The abortion of inflammation is now much advanced by the progressing knowledge of asepis. Pyæmia, the opprobrium of surgery, has been enormously reduced in frequency. When suppuration has occurred evacu-

ation, drainage and antiseptics have been equally successful in shortening the pyogenic process and in promoting repair. In tubercle we see the best results follow the évidement of Sedillot, both in cancerous bone and in suppurating lymphatics.

As in variola, may we not hope that a modified germ may jugulate the tubercle bacillus, by inoculation? or if we meet not the success which the modification of rabies is slowly attaining, that chemistry may give us a reagent to devitalize the germ of tuberculosis.

Cancer, to include under that term all recurrent tumors, is, by Virchow's nomenclature, a misplaced cell growth. Modern research now gives us hope of finding the cause of this maldevelopment, and if a germ should be discovered here, a germicide will be finally found.

The manual part of our art—surgery, handcraft, requires also to be perfected, in connection with the advancing boldness with which we open cavities and feel the pulse of life in its central shrine. New operations demand a new technique, new modes, new instruments, a new code of rules; all to be learned by experiment. Nowhere, perhaps, could the French saying, "*jeur chirurgien, vieux medecin*," be more applicable. It is to the young surgeon, born and bred in asepis, that the older physician must look for progress in our art.

In estimating, then, the limitations of surgery, we find none, except they be set by ourselves. How should they be set? By conservative judgment opposed to rashness. In the list of modern and useful operations as distinguished from those barely justifiable, are the following:

1. To remove growths or foreign bodies from the cavities of the body: Opening the brain; opening the spinal cord; displacement of the upper jaw or of the nose for nasopharyngeal polypi; cutting into the pharynx from outside the neck to remove tumors of the tonsil; œsophagotomy for foreign bodies; thyrotomy for growths; gastrotomy for foreign bodies; opening the gall bladder for the removal of stones; opening the pelvis of the kidney for calculi; suprapubic cystotomy for calculi and tumors of the bladder; ovariectomy; removal of the diseased uterus or its appendages; laparotomy for gunshot wounds, and for extra-uterine fetation; excision of the lower part of the rectum for growths.

2. To reach and evacuate inflammatory products: Opening the chest and resecting the ribs for empyema; opening the abdomen for appendicitis, or for chronic peritonitis; opening and drainage of pelvic abscesses; of abscess of the vertebrae; opening of deep abscesses of the neck; evacuation and draining abscesses of joints; perinephritic abscess and removal of one kidney.

3. To relieve obstruction: Intubation and tracheotomy; gastrostomy and enterostomy; colotomy; perineal section; herniotomy.

4. To restore continuity: Resection and suture

of bowel; resection and union of bones; resection and reunion of nerves; nerve grafting; reunion of tendons and of muscles.

5. Unclassified procedures: Plastic and osteoplastic surgery, modifications of orthopædies, including bone resections and excisions; litholapaxy; reduction of dislocation of the hip and of the shoulder by applied anatomy; endoscopy; rhinoscopy and removal of turbinated outgrowths; pathology and removal of adenoids; aseptic wiring of fractures; local anæsthesia in setting fractures; closing of skull wounds by the insertion of buttons of bone.

6. Operations as yet *sub judice* or on trial: Resection of pylorus; resection of cancerous intestine or omentum; removal of the spleen; of large bronchoceles; of the larynx; the pancreas; the prostate gland; the normal ovary; fixation of the kidney or of the uterus; puncture of the pericardium; opening gangrenous abscesses in the lung; tapping the ventricles of the brain.

Rash statements are to be discounted; rash operations are to be discouraged. The wisdom of our earliest Greek master in analyzing the imperfection of our art holds true to-day: "*Arx longa, cila brevis est; occasio fugax, experimentia foliæ; judicium difficile.*" Yet with Bacon came the new light of experiment. In his immortal words: "*Recte veritas temporis filia dicitur, non auctoritas.*" Lean not on authority; the test of truth is time.

The death of Dr. S. W. Gross, of Philadelphia, was reported, and Drs. D. W. Vandell, J. Ewing Mears and P. S. Conner were appointed a committee to prepare appropriate resolutions.

The Committee on Nomination was announced as consisting of Drs. D. Hayes Agnew, Wm. T. Briggs, Hunter McGuire, John S. Billings and J. R. Weist.

On motion of Dr. L. McLane Tiffany, the Secretary was requested to wire to Dr. T. G. Richardson, of New Orleans, the senior Vice-President, who was prevented by illness from attending the meeting, the regrets of the Association at his absence.

DR. DAVID W. CHEEVER, of Boston, read a paper on

SARCOMA OF THE TONSIL—EXCISION.

The patient, a male, æt. 57, single, for one year had to breathe through the mouth on account of enlargement of the left tonsil. No pain was experienced until November 1, 1888, when he "caught cold" and the tonsil swelled considerably and became sore and tender, and discharged spontaneously a few days later. At the same time he noticed some enlarged glands in the left neck. The glands gradually increased in size. The tonsil caused no more pain but there was an increasing sense of fulness behind it, increasing

dysphagia and difficulty in articulation. There was loss of appetite and weight. When he came under observation January 14, 1889, the left tonsil was found to project nearly to the uvula, and was as large as a pullet's egg. There were two glands in the left neck each as large as a horse-chestnut.

The operation was performed January 17, 1889, ether being given, and the patient being in a sitting posture. A gland in front and one behind the sterno-cleido mastoid muscle were removed. The first incision was semi-lunar, concave upwards, marking the boundaries of the digastric triangle. A second incision over the lower jaw at right angles to the middle of the first incision was then made. The right hyoid muscle was now divided and the other tissues pushed to one side. The lower jaw was then sawed in two in front of masseter muscle. The tumor was pressed out by finger in the mouth, and was found to be covered with a delicate capsule. On puncture a soft material exuded. The tumor and capsule were removed without great difficulty. There was no hemorrhage and the facial artery and external jugular veins the only vessels ligatured. The wound in pharynx was not sewed; the jaw was wired, the external wound in skin was wired, the external wound in skin was partially approximated and washed with two per cent. boracic acid solution, and dressed with boracic gauze. The wound was dressed daily. Healing took place rapidly, with no unfavorable symptoms. On the 30th day the wire was removed and the jaw found to be firmly united. Microscopical examination showed the growth to be round cell sarcoma.

April 27, a second operation was performed for a tumor on the same side of the neck. The throat, however, remains healthy. A large glandular mass was removed from anterior carotid triangle. This also proved to be a round cell sarcoma.

DR. D. HAYES AGREW, of Philadelphia: There are several points of interest in connection with sarcoma of the tonsil. I think that including the case of Dr. Cheever's there are only ten or eleven on record. A second point is the fact of constant recurrence. I believe that there is only one case on record where return has not taken place. In that case the thermo-cautery was employed. Various operations have been employed, enucleation, the écraseur, the galvano-cautery, the thermo-cautery, and the external method first used by Dr. Cheever. The operations when undertaken should be done simply with the view of palliation. The operation from without is confessedly a difficult operation, and while in the hands of experts it probably affords the best opportunity for the removal of all diseased structure, but for the general operator some other method would no doubt be better. I have been much struck with the exposure gained by simply slitting the

cheek in operations on tumors far back in the throat, as far back as the soft palate. This would probably give as good a chance of success as any other plan of procedure.

DR. A. VANDERVEER, of Albany: The first well marked case of sarcoma of the tonsil that has come under my observation was in a man aged 72 years. The tumor had been discovered four months before I saw him. There was a full, round tumor of the tonsil, interfering seriously with deglutition and somewhat with breathing. The patient selected enucleation in preference to the operation from the outside. My intention was to remove all that I could with the tonsilotome cutting from behind forward, then enucleate with a blunt instrument and use the thermo-cautery. After cutting through the capsule the tonsilotome slipped behind the tonsil and it was completely enucleated. I did not apply the thermo-cautery. The patient had no return of the disease for eight months. The growth then reappeared and rapidly increased in size. Two months later the patient was taken with pneumonia and died in a few days.

DR. P. S. CONNER, of Cincinnati: I think that the statements in reference to the infrequency of sarcoma of the tonsil are hardly correct. I know of several unreported cases, two of which came under my own observation. One was in a girl aged 26 years. The disease was so far advanced that I thought no operation justifiable and she died a few days later. The second case was a man aged 40 years. The tumor was as large as the fist. I operated by slitting the cheek and was able to readily separate the tumor from the capsule with the finger. The operation was done in June. In July he was apparently in excellent condition. The disease began to recur in the latter part of August and grew rapidly, and in October he was found dead in bed, supposed to have committed suicide.

DR. M. H. RICHARDSON, of Boston: Some time ago I removed a sarcoma of the tonsil by external incision. The enucleation was accomplished with ease and without opening the pharynx. A year after the operation there had been no return of the disease. This was two years ago, and as far as I know the patient is still living.

DR. CHEEVER: The operation through the cheek is probably easier and more desirable in some cases, but the operation from the outside leaves less paralysis and less scar. The great dread of these operations opening the upper part of the alimentary canal was formerly the danger of fistula. This has now been proven to be without foundation. I am inclined to think that the use of sutures in the pharynx or œsophagus would be more dangerous than their omission. The object of these operations is to permit the patient to die easier. It is more comfortable to

die with an external tumor than with one pressing upon the larynx or throat, causing starvation or choking.

(To be concluded.)

FOREIGN CORRESPONDENCE.

LETTER FROM PARIS.

(FROM OUR SPECIAL CORRESPONDENT.)

Hyperthermic Gastric Disorders and their Treatment by Naphthol—Salicylate of Soda as an Antipyretic—The Proscription of Ergot of Rye during the After Stages of Parturition—Maladies of the Organ of Vision produced by Diabetes and the Indications for Operative Measures—The Abortive Treatment of Whitlow.

At a recent meeting of the Clinical Society, Dr. Comby, Hospital Physician, read a note on *Hyperthermic Gastric Disorders and their Treatment by Naphthol*, from which the patients derived the greatest benefit. Following the example of Professor Bouchard, who vaunted this substance in intestinal disorders, Dr. Comby prescribed naphthol B. in doses of 2 grams, 50 centigrams per day. One patient was a young man, aged 21 years, a house painter, and who was formerly subject to lead colic, but had not for some months past been exposed to saturnine intoxication. At the time of his applying for advice he was dyspeptic, had dilatation of the stomach, and had, at the second phalanges of the fingers, in a very marked degree, osseous nodosities, which Professor Bouchard was the first who studied them, and of which he fixed the semiological value. This condition was accompanied by a high body temperature, rising as high as 41.2° C., but the day after the administration of the naphthol the temperature fell to 37.2 C., and only but once rose again, when it marked 38.3° C. In another case of febrile gastric trouble, accompanied with incessant bilious vomiting, the naphthol produced marvelous effects. According to Dr. Comby's experience, naphthol is an inoffensive medication, and may be employed for some time without any inconvenience, and he can only corroborate the observations of Professor Bouchard, who stated that intestinal antiseptic in general, and antiseptic by naphthol in particular, should be practiced in all these morbid states which, as for instance, gastric disorders, appear to depend on abnormal putrefactions which occur in the digestive tube.

Professor Jaccoud, at a recent clinical lecture, stated that, according to his experience, the best antipyretic, in febrile tuberculosis, is the salicylate of soda. He considers it inadmissible, that in presence of the facts brought out by clinical experience that the sulphate of quinine should still be administered in these cases. The salicylate

of soda should be given at a maximum dose of 2 grams in 24 hours. At a daily dose of 1 gram the medicament may be advantageously continued for a long time, with this precaution that the patient should absorb, after each dose or part of a dose, largely diluted with plain or alcoholized water. The contra-indications of the use of the salicylate of soda are: affections of the kidneys, inflammation of the lungs (for fear of asphyxia), and of the heart.

According to Dr. Blanc, of Lyons, the proscription of the use of the ergot of rye, which is the rule during pregnancy and labor, should be extended to the after stages of parturition, except of course in certain cases. Of ninety-two women, whom the author divided into three categories, he studied the influence of ergotine on uterine regression. The first forty had no ergotine, he simply contented himself with measuring the length of the uterus in the first ten days. Forty women also served for experiment in the second category. To each he administered one gram of ergotine Yvon in subcutaneous injection in the abdominal parietes, for ten days following parturition. In the twelve others the same treatment was employed during ten days. It results from these researches that there was scarcely any appreciable difference in the mensurations of the uterus whether ergotine was or was not employed. Dr. Blanc, therefore, feels authorized to say that involution is better accomplished when there is abstention, and he concludes his note as follows: 1. That ergotine, employed during the first five days, has no influence whatever on the regression of the uterus. 2. That this medicament, employed after parturition, may oppose, in a certain measure, the retraction of the organ. This medicament, already proscribed during pregnancy and during labor, should equally be proscribed during post-partum, except, however, in the case of secondary hemorrhage, where its action is the more sensible the nearer the confinement.

In a note by Dr. Stæber in *The Journal d'Oculistique*, the author examines the maladies of the organ of vision produced by diabetes, and the indications for operative measures. The lesions of the organs of vision produced by diabetes are, he said, of seven species: 1. The anomalies of accommodation and of refraction. 2. Cataracts. 3. Troubles and hemorrhages of the vitreous body. 4. Hemorrhagic retinitis. 5. Atrophy of the optic nerve. 6. Paresis of the extrinsic muscles of the eye. 7. Keratitis more or less grave. In referring to the operative indications the author had particularly in view the operation for cataract. He ranges himself to the opinion of those ophthalmologists who practice extraction, whatever be the quantity of sugar contained in the urine, abstaining from operating only when the state of emaciation and of debility has reached a too high degree.

The author, however, recommends the previous treatment of diabetes, and advises that the operation should be performed only when one had obtained by this treatment a notable diminution in the quantity of sugar contained in the urine. He recommends all the antiseptic precautions before and after the operation. The surgeon will abstain from all surgical intervention, if there exist at the same time as the cataract, a grave amblyopia, symptomatic hemorrhages of the retina, or atrophy of the optic nerve.

Dr. Gaucher, in writing on the abortive treatment of whitlow, states that, to effect this object, it is sufficient to moisten slightly the painful part and around it with a little water, and to pass over this surface a stick of nitrate of silver. In a few hours after the skin becomes black, all pain disappears and the inflammation is arrested. No dressing is required and the black color disappears in six days. The author relates that in a case of the fit of the gout, the great toe was much swollen and painful to the touch, rather red, and was the seat of lancinating pains which prevented the patient from sleeping. The toe was painted as above described, and the next day it diminished in size, the pain completely disappeared a quarter of an hour after the painting, and the patient got up and attended to his occupation. A. B.

A LETTER FROM MOSCOW.

Artificial Inoculation of Calves.

From "*Le Progrès Médical*" of April 27, 1889.

To the Editor in Chief:—At the last session of the Société physico-médicale de Moscow, Dr. A. Voitoff made a communication of much interest on the *Artificial Vaccination of Calves*. In spite of numerous researches, no one has yet discovered the pathogenic microbe of small-pox. Studying this interesting question and endeavoring to find the specific agent of this disease, M. Voitoff has found in the contents of variolous pustules the presence of some species of microorganisms which are already known and described. Inoculations of calves with cultures of each one of these microbes gave no results. M. Voitoff employed an injection of a mixture of the cultures with satisfactory results. Animals vaccinated in this way presented characteristic variolous pustules. (A vaccinated calf was shown to the Society.) The reinjection from this first animal of others has always produced variola. Experiments with genuine variolic lymph show that animals vaccinated with the artificial lymph had entire immunity from the disease. It was remarked that at the fourth generation the artificial lymph began to lose its virulence. The members of our Society for the most part admit that the observations of

M. Voïtoff merit a position among the great discoveries.

This study proves in fact that an infectious disease may be excited not only by one pathogenic microorganism, but also by the simultaneous presence in the organism (by symbiosis) of microbes which taken alone would be harmless. Besides this, artificial vaccination, now possible after the methods of M. Voïtoff, would free us from all danger of the introduction of the virus of other diseases, as syphilis, tuberculosis, etc.

S. VERNEL.

Moscow, April 10, 1889.

As the above letter seemed of much interest I have translated it for THE JOURNAL.

THOS. M. FLANDRAU, M.D.

Rome, N. Y., May 15, 1889.

DOMESTIC CORRESPONDENCE.

Etiology of Pulmonary Phthisis.

Dear Sir:—Referring to your kind review (on pages 629 and 630) of my paper, read before the Section on Climatology, etc., International Medical Congress, it does seem *possible*, as you suggest, that those deaths from phthisis which are controlled by the atmospheric temperature are the cases of chronic pneumonia "catarrhal phthisis," and it may not be practicable to prove or disprove this assumption until after distinctions between that disease and tubercular phthisis are made in mortality reports; yet we have strong evidence bearing upon the subject, as follows: My tables and diagrams show positively that scarlet fever and small-pox are quantitatively controlled by the atmospheric temperature; and there can be little, if any, doubt that this is because the specific contagia of these diseases find easiest entrances, by way of the air-passages, when the exudative inflammations in the air-passages are most prevalent, that is, during the coldest weather: at such times, then, inoculation with the specific contagia of these diseases occurs, and, in susceptible persons, these diseases are thus caused. We have reason to believe that, just as the inoculation with the specific contagia of scarlet fever and small-pox occurs most when the air-passages are most irritated, so inoculation with any other contagium which can enter by way of the air-passages will occur when the air-passages are most irritated; and it is proved by my tables and diagrams that this is in the coldest weather. It is known that the *bacillus tuberculosis* is present in the dust of rooms inhabited by consumptives where the sputa are not carefully collected in cups or spittoons. And, although the bacilli are not in the air expired by consumptives, there can be little doubt

that the bacillus is frequently present in the dust of public halls, on the floors of which sputa may be dried. It is now well known that inoculation with the *bacillus tuberculosis* causes tuberculosis in susceptible persons and animals. That the deaths reported from phthisis pulmonalis are controlled, as they are to some extent, by the atmospheric temperature, seems to me to be because in some cases the deaths follow within a few months of the inoculation, which in some cases is, as I believe, by the inhalation of the bacillus, and, in some cases, by the exudation and rapid multiplication of bacilli in the inflammatory exudates (in the lungs and air-passages), caused by the inhalation of cold dry air, and thus deaths from phthisis *pulmonalis* result to persons who have previously had tuberculous disease in some part of the body. But, that a larger proportion of the sickness from consumption is not, apparently, controlled by the atmospheric temperature, seems to me to be because of the long and extremely variable duration of the disease after first inoculation with it, coupled with the fact that the reports of sickness include old cases as well as new cases. If the sickness could be learned so as to include in the report only the new cases taken sick, I think a very large proportion of all the cases would be found to be quantitatively related to the atmospheric temperature, just as is found true for scarlet fever and small-pox, in which diseases only cases recently taken sick can be included.

With deference to the author of the editorial, I respectfully submit that if it is a fact "that the highest ratio of phthisis to the population is in the North-Eastern and Middle States;" that fact is not evidence that the climatic causes of phthisis are most present in the Middle and North-Eastern States; on the contrary, they may be least present there, because the death-rate from phthisis increases so rapidly with the age of inhabitants, over the age of fifty years.¹ So that a comparison of the total death-rates from phthisis at all ages in different localities may supply a hint as to the average age of the inhabitants, but cannot supply evidence of the comparative healthfulness of the localities, unless it is shown that the ages of the inhabitants in the several localities are the same, and then it cannot, unless it is shown that in these populations the proportion of the sexes at the different ages are the same. Even then, the evidence from comparisons of places has little value, unless it is shown that the occupations and character of the inhabitants are the same, because phthisis is less fatal among the well-to-do who are not in certain dangerous occupations, and it is lessened, as stated in the editorial, by drainage and by sanitary conditions. I submit that nothing has been established as to the geographical distribution of phthisis, which is important that my facts or my "explanations"

¹ Vital Statistics of Michigan, 1870, pages 314-315.

tion be reconciled with," except the fact, referred to in the editorial as having been established by Dr. Henry I. Bowditch, in this country, and by Dr. Buchanan, in England, that residence over low, undrained soil is conducive to phthisis. But it is an error to suppose that the facts which I have presented are not in harmony with those presented by Drs. Bowditch and Buchanan. They are all in harmony, and are easily reconciled, as I shall try to point out in a paper to be read before the Section on State Medicine at the coming meeting of the Association, at Newport, R. I.

If "the highest ratio of pneumonia is on the lower part of the Atlantic slope between the Delaware and Savannah, etc., the explanation may be similar to that just suggested as to phthisis, the mortality from pneumonia is much greater at some ages than at others, it is especially great among children, and, in adults, more among males than among females, therefore comparisons of localities teach us little unless a great many facts besides the total death-rates are given, and such facts have not yet been supplied.

The answer to the last sentence in the editorial (page 630), is of considerable interest, because it is "new to science." If one will study carefully the diagram, graphically representing the facts exhibited in the tables in my article reviewed in *THE JOURNAL*, it will be seen that it is certainly proved not only that the prevalence of such diseases as influenza, croup, scarlet fever and small-pox, is controlled by the temperature, that the times of maximum and minimum prevalence of each specified disease follow the times of greatest and least cold, but that the disease is later than the exposure to cold by a time equal to the average duration of the disease, and the period of incubation, if it have one. Thus, the maximum sickness from such an acute disease as croup (Diagram 13) is in the same month as is the greatest exposure to cold atmosphere, and the least sickness is in the month of least cold, the most sickness from scarlet fever and from pneumonia is a month later, and the least sickness from each disease is a month later, while the changes in the deaths from small-pox and from phthisis (Diagrams 9 and 10) follow (in most months of the year) about two or three months later than the atmospheric temperature changes. Deaths from small-pox should be expected to follow, and they seem to follow, as long a time later than the temperature changes as is the average duration of the fatal cases, plus the average period of incubation. Similar remarks may be made of phthisis pulmonalis; probably because, whether the tubercular disease of the lung is incited by bacilli inhaled into the lungs, or by bacilli which reach the lungs through the blood from some other part of the body of a tuberculous person, the irritations and exudations, which enable the bacillus to reproduce rapidly in the lungs, and make it

possible for this disease to cause deaths from *pulmonary* disease, seem unmistakably to follow the exposure to inhalation of cold atmospheres, considerable portions (about one-sixth) of both the sickness and the deaths from pulmonary consumption follow about two or three months after the changes in the temperature of the atmosphere; that the proportions which are apparently controlled by the atmospheric temperature is, as I believe, owing to the long and variable duration of the disease, as I have already explained.

Thus far no one has collected and published very many facts concerning the first onset of phthisis pulmonalis, and has studied those facts in their relations to the inhalation of cold dry air, and in relation to the inhalation of dust containing the *bacillus tuberculosis*; but I submit that the facts which I have published, taken in connection with what is the common property of the profession, make it extremely probable that the causation of pulmonary phthisis is thus to be explained.

Very respectfully,

HENRY B. BAKER.

Lausing, Mich., May 11, 1889.

MISCELLANY.

THE MITCHELL (IND.) DISTRICT MEDICAL SOCIETY will meet at West Baden, Ind., Thursday and Friday, June 13 and 14, 1889. Papers of interest to the entire profession will be presented at the meeting. Reduced rates on railroads have been secured. Special hotel rates.

THE CHAMPAIGN COUNTY MEDICAL SOCIETY met May 5th, at Mosgrove Lodge Hall, Urbana, Ohio, with a large number of members and visitors present. After the examination and discussion of several clinical cases presented by members of the Society, Prof. D. N. Kinsman, of the Columbus Medical College, Columbus, Ohio, who was present by invitation, was introduced by the President, and delivered a very able and instructive discourse on the subject of *Microbes*. The lecture was listened to with great interest by all present. Dr. Kinsman was unanimously tendered a vote of thanks by the Society, and invited to return again at some future time and continue the subject.

THE German Government has not only refused to open fresh schools of medicine, but the *Landtag* has refused the subsidies formerly accorded to certain professorial chairs at Halle and Marburg.—*The Practitioner*.

THE honorary degree of Doctor of Laws has been conferred by the Senatus Academicus, Edinburgh University, on Dr. Richard Quain, of London.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from May 11, 1889, to May 18, 1889.

By direction of the acting Secretary of War, a board of medical officers, to consist of Lieut.-Col. Anthony Heeger, Surgeon, Capt. F. C. Ainsworth, Asst. Surgeon, and Capt. John O. Skinner, Asst. Surgeon, will assemble at the U. S. Military Academy, West Point, N. Y., on June 1, 1889, to examine into the physical qualifications of candidates for admission, and members of the graduating class. Par. 9, S. O. 108, A. G. O., May 10, 1889.

By direction of the acting Secretary of War, the following named officers are detailed to represent the Medical Department of the Army at the annual meeting of the American Medical Association to be held at Newport, R. I., on June 25, 1889: Major Samuel M. Horton, Major John S. Billings and Major Charles Smart, Surgeons U. S. Army. Par. 15, S. O. 110, A. G. O., May 13, 1889.

By direction of the acting Secretary of War, the ordinary leave of absence granted Capt. William B. Davis, Asst. Surgeon, in S. O. 232, October 5, 1888, from this office, is extended six months on surgeon's certificate of disability. Par. 20, S. O. 180, A. G. O., May 10, 1889.

By direction of the acting Secretary of War, leave of absence for six months, on surgeon's certificate of disability, is granted Capt. R. G. Ebert and Capt. E. B. Moseley, Asst. Surgeons U. S. Army. Pars. 5 and 6, S. O. 109, A. G. O., May 11, 1889.

By direction of the acting Secretary of War, Capt. Louis S. Tesson, Asst. Surgeon U. S. Army, is relieved from duty at Watervliet Arsenal, N. Y., and ordered to Ft. Sidney, Neb. Par. 9, S. O. 107, A. G. O., May 11, 1889.

Capt. William C. Gorgas, Asst. Surgeon, now on duty at Ft. Barrancas, Fla., will report in person to the commanding General, Dept. of the Missouri, for temporary duty with troops in the field. Par. 1, S. O. 112, A. G. O., Washington, May 15, 1889.

Capt. Wm. C. Gorgas, Asst. Surgeon U. S. Army, ordered to proceed at once and to report to the commanding General Dept. of the Missouri for temporary duty in the field.

Capt. Wm. C. Gorgas, Asst. Surgeon U. S. Army, will accompany the command from Ft. Barrancas, Fla., and proceed with battery H., Second Artillery, to Ft. Adams, R. I., and to return to his proper station on completion of this duty. Par. 5, S. O. 108, Hdqrs. Div. of the Atlantic, Governor's Island, New York City, May 13, 1889.

First Lieut. Jefferson R. Kean, Asst. Surgeon U. S. Army (Ft. Robinson, Neb.), is hereby granted leave of absence for one month, to take effect between the 1st and the 15th of June, 1889, with permission to apply at Hdqrs. Div. of the Missouri for an extension of fifteen days. Par. 2, S. O. 48, Hdqrs. Dept. of the Platte, May 13, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending May 18, 1889.

P. A. Surgeon Robert Whiting, ordered to the receiving ship "Minnesota."

Surgeon G. E. H. Harmon, detached from the Naval Academy and to the "Constellation."

Asst. Surgeon C. W. F. Lowndes, detached from Naval Academy and to the "Constellation."

Asst. Surgeon W. F. Arnold, detached from the "New Hampshire" and to the "Pinta."

P. A. Surgeon C. W. Rush, detached from the "Pinta," proceed home and wait orders.

Surgeon W. A. McClurg, ordered to the Bureau of Medicine and Surgery.

Asst. Surgeon E. R. Stitt, detached from Bureau Medicine and Surgery, and to the "New Hampshire."

Surgeon H. C. Eckstein, ordered to the Marine Rendezvous, Philadelphia, Pa.

Medical Director M. Bradley, detached from Marine Rendezvous, Philadelphia, Pa., and continue on special duty at Philadelphia.

Surgeon M. L. Ruth, granted another year's leave.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Four Weeks Ending May 11, 1889.

Surgeon George Purviance, detailed as chairman of Board for the physical examination of candidates for appointment as cadets, Revenue Marine Service. May 3, 1889. Detailed as chairman of Board for the physical examination of officers, Revenue Marine Service. May 11, 1889.

Surgeon Fairfax Irwin, to proceed to Bath, Wiscasset, Rockland, Belfast, Bangor, Ellsworth, Machias, and Eastport, Me., as inspector. April 22, 1889.

P. A. Surgeon F. W. Meade, detailed as recorder of Board for the physical examination of candidates for appointment as cadets, Revenue Marine Service. May 3, 1889. Detailed as recorder of Board for the physical examination of officers, Revenue Marine Service. May 11, 1889.

P. A. Surgeon W. A. Wheeler, granted leave of absence for thirty days. April 16, 1889.

P. A. Surgeon W. D. Bratton, relieved from duty at San Francisco, Cal.; to assume charge of the Service at Portland, Ore. May 8, 1889.

Asst. Surgeon G. M. Magruder, to proceed to Baltimore, Me., for duty. May 8, 1889.

Asst. Surgeon T. B. Perry, when relieved at Portland, Ore., to proceed to San Francisco, Cal., and await orders. May 8, 1889. To report to the commanding officer, revenue str. "Rush," for special duty. May 11, 1889.

Asst. Surgeon A. W. Condict, when relieved from duty at Boston, Mass., to await orders. May 8, 1889. To report to the commanding officer, revenue str. "Chase," for special duty. May 11, 1889.

Asst. Surgeon S. H. Hussey, when relieved from duty at Baltimore, Md., to proceed to Boston, Mass., for duty. May 8, 1889.

Asst. Surgeon H. D. Geddings, to proceed to Baltimore, Md., for temporary duty. May 8, 1889.

ADDRESS.

PRESIDENTIAL ADDRESS.

Delivered before the Kentucky State Medical Society at its Thirty-Fourth Annual Session, held in Richmond, May 8, 9, and 10, 1889.

BY L. S. McMURTRY, A.M., M.D.

Fellow-Members of the Kentucky State Medical Society.—Thirty-eight years have elapsed since a convention of Physicians of Kentucky was held in the Senate-Chamber at Frankfort, to consider the necessity of organizing a State Medical Society. In effecting permanent organization, the constitution, which was a model of simplicity and conciseness, declared the purposes of the organization in this language:

"First. The cultivation and advancement of medical science and literature by the collection, diffusion, interchange, presentation, and general circulation of medical knowledge throughout the State.

"Second. The establishment and maintenance of union, harmony, and good government among its members, thereby promoting the character and usefulness of the profession."

In October, 1852, the second annual meeting of the society was held in the circuit court room in Louisville, when the real work of the society was inaugurated. At this meeting the original members were nineteen in number, and included the familiar and memorable names of Breckinridge, Chipley, Dudley, Flint, Foree, Gross, Miller, Letcher, Richardson, Sutton, Sneed, and Spillman. Forty-six physicians were added to the membership at this meeting, among others the names of Bell, Caldwell, Ewing, Hewitt, L. P. Vandell, Lewis Rogers, Powell, Bartlett, Wible, Peter, and Bullitt are found, names familiar to Kentucky people and to students of medical science.

At this meeting Professor Henry Miller made a report on the progress of Obstetrics, a duty for which his original work and superior knowledge eminently fitted him; and Professor Gross read his famous report on Kentucky Surgery. Dr. W. S. Chipley contributed a report on Vital Statistics, in which he gave an exhaustive report of the sanitary condition of the State, illustrated

by a valuable map prepared under his direction, the result of a sanitary survey of the State. The counties are arranged in colors with reference to their mortality and the prevalence of disease. Dr. C. H. Spillman, of Harrodsburg, who is still among us respected and honored, made an elaborate report on the Indigenous Botany of Kentucky. The first volume of Transactions was indeed a valuable contribution to medical science and literature. The work done at this meeting demonstrated the facts: First, that an organization for promoting the science of medicine and improving the sanitary condition of our people was needed; second, that the profession in Kentucky was thoroughly imbued with the scientific spirit, and in ability, culture and attainments conspicuously in advance of the age.

Briefly and imperfectly I have sketched the origin and foundation of the society which has assembled here this evening in its 34th annual session. At the time to which I have referred—1852—there were 982,405 inhabitants in the State of Kentucky, and 1,470 physicians. In Lexington, afterward removed to Louisville, a centre of medical education had already been established, drawing to its instructions large numbers of pupils from the great domain west and south of the Alleghanies. The fame of McDowell, Dudley, Drake, Caldwell, Gross and their colleagues had already extended far and near. These were the surroundings and the fields in which our predecessors labored. And now that thirty-eight years have elapsed, with regular annual meetings, save during the four years of civil war, may we not pertinently inquire, what has been accomplished? How can we of the present, best discharge the duty committed to us by our predecessors? What of the future? These are questions which well deserve our thoughtful consideration.

As has already been stated the original constitution declares the chief and first purpose of this organization to be "the cultivation and advancement of medical science and literature, by the collection, diffusion, interchange, preservation, and general circulation of medical knowledge throughout the State." The earnestness of this purpose was attested in 1852 by the historic papers already mentioned, which may be found in the first volume of our Transactions. The time at my command will

not permit even an enumeration of the many important contributions to medical science and literature made through the medium of this society and published in the Transactions through all these years. Elaborate researches and clinical studies bearing upon the various departments of pathology, surgery, and midwifery constitute the major portion of the Transactions. Through the several standing and special committees all the great advances in medical science and every improvement in the art of medicine and surgery have been quickly brought to the attention of the society. Papers bearing upon improvements in medical education have found a place almost every year, and questions relating to Sanitary Science have been a conspicuous feature of our proceedings. By oft-repeated suggestion and indefatigable labor through appropriate committees, the act of the General Assembly establishing the State Board of Health was secured, more recently by the exertion of the able and efficient executive officer of the Board of Health, with the active coöperation of this society, our legislature was brought to realize the importance of further protecting the public health, and passed a law regulating the practice of medicine in this Commonwealth. The custom of holding the annual meetings at various points in the State, observed since the foundation of the society, has of itself promoted the declared purpose of the society by awaking the profession's interest in scientific work and diffusing knowledge. By this means too, county medical societies have been developed and encouraged.

The second purpose enunciated in the constitution relates to elevating the character of the profession. Through this society, from its foundation to the present time, appeals have been constantly made for elevating the standard of professional rectitude, and exposing the evils of charlatantry.

If time and patience permitted, I might enumerate many of the indirect influences exerted by this society in diffusing knowledge, improving the resources of our art, and advancing the public welfare. The charitable institutions of our State have at all times elicited the interest of our society. Our delegates have annually occupied their places in the American Medical Association, and contributed liberally to its proceedings.

From what I have stated relative to the status of the profession in Kentucky at the time this body was organized, it is seen that the standard of Kentucky medicine was conspicuously high. The metropolis of the State has continued to be, and is now, a centre of medical education for the south-west. The medical periodicals edited and published in Kentucky are numerous and of a high order of scientific merit. To these the members of this society have been constant contributors. In 1879 it was decided by the society

that its papers and proceedings could be best disseminated through the medical journals of the State, and the annual volume of Transactions was discontinued. The last volume published by the society was the McDowell Memorial volume, containing the oration of Professor Gross and other papers incident to the dedication of the McDowell monument which was erected by the society in Danville in 1879.

An examination of the series of volumes entitled the "Transactions of the Kentucky State Medical Society" enables one to trace the progress of medicine through these years of activity in every department of our art. As knowledge grew apace, and concentration of energy with the necessary division of labor obtained, specialists in medical practice were developed. These gentlemen representing the various specialties, have been for years past the most active and valued contributors to the work of the annual sessions. At the same time the great body of the society is composed of general practitioners, whose studies and observations in general medicine and surgery compose the greater portion of our proceedings and are equally instructive and valuable. Indeed, here, as elsewhere in our profession, many of the most important and original contributions to medical science have emanated from the practical country doctor. So it obtains that the specialist brings here the results of his expert training and concentrated labor to enrich the knowledge of the general practitioner; while the general practitioner strengthens and enlarges the specialist's knowledge in those lines wherein his work began, and with which his special work is of necessity closely related. In thus glancing hastily back over the thirty-three annual meetings, it is not my purpose to present an optimistic view of our society's labors and their results. Perfection is seldom attained in human institutions or human efforts. There are many features of our annual meetings which could be improved. Each year witnesses improvement in some part of our exercises. This is probably most notable of late in the large number of papers presented at the meetings, in the discussions arranged beforehand by the Secretary, and the improved arrangements for reporting and publishing the papers and discussions.

It would also be unfaithful to the record to depict our society's history as a smooth career of harmonious discussion and unanimity of sentiment, opinion and desire. Numerous breezes and some storms have swept across our floor, but these are necessary to progress, and doubtless purify the atmosphere and encourage wholesome growth.

Our organization has not been without its critics and reformers. They are both within and without. The occasional attendant, who seldom, if ever, contributes a paper or participates in the

discussions, expresses his disapproval of those most active in the society's proceedings, claiming that they monopolize the time of the society; forgetting that the attention of the society can be readily had by himself whenever he chooses, unmindful apparently that the most active members are those who make the society what it is, and extend its usefulness. The reformer often appears upon the floor with resolutions to amend the rules and mode of organization of the society, only to show oftentimes that he has not carefully read our constitution and by-laws. From time to time a momentary enthusiasm appears in the form of a proposition to organize a new State Society upon some ideal basis, forgetting that such institutions are built up through years of steady labor, and cannot be created in full vigor in a night; and overlooking the important fact that any suggestions looking to improved efficiency are sure of respectful attention upon this floor. The most certain and the speediest way to improve the efficiency of the society, is to attend the annual meetings, and take part in the discussions. If in 1851 in our sparsely settled State our predecessors realized the necessity of organization for the cultivation of medical science, surely the obligation to enrich and improve the efficiency of that organization is now increased. The population of Kentucky has almost been doubled, the number of physicians greatly increased, and the science and practice of medicine and surgery advanced to a degree of perfection beyond the most sanguine expectations of the past generation. In all departments of our art is to be seen the greatest activity, and never before in the history of medicine was there such a demand upon the physician's powers to keep abreast in the line of advance.

ORIGINAL ARTICLES.

PRIMARY SARCOMA OF THE LUNG.

BY A. F. BOCK, M.D.,
OF ST. LOUIS, MO.

On the 13th of September, 1888, I was called to see Bertha F., æt. 5, of German parentage. Family history exceptionally good, parents strong and healthy. Patient had four sisters and one brother, all healthy. Grandparents still living with the exception of the maternal grandmother, who died about two years ago of chronic senile gangrene. According to the mother's statement the child had been ill since about July 20 last, when she was taken with a high fever (105°) and complained of severe pain in her left side; which continued with more or less severity until she died. As the fever yielded to quinine it was no doubt of malarial origin. While under my ob-

servation there was no increase of temperature, no cough nor expectoration. The right half of the body was constantly bathed in perspiration, the left always dry. There was very little desire for food, but no difficulty in swallowing. Sleep much disturbed by dyspnea. Pulse ranged between 95 and 110. Previous to July 20 the child had been enjoying good health with the exception of occasional slight ailments. Inspection showed the left thorax considerably increased in size, the intercostal spaces not flattened but stretched; œdema very slight. No movements of the affected side on inspiration and expiration, but a fulness in the epigastrium as if the diaphragm were thrust downwards and forwards. The superficial veins over the left thorax, face and neck were distended. Emaciation of the whole body very marked. Percussion sound flat over the entire area of left lung. Auscultation of the affected lung showed total silence in regard to respiratory sounds. Heart sounds and beat were to the right of the sternum and below the nipple somewhat accelerated and weak, but otherwise normal. Palpation showed absence of vocal thrill.

The history, symptoms and physical signs in this case coincided so closely with those of empyema that Drs. Mullhall and Ostertag, who were called in consultation, concurred in the opinion that the phenomena which the patient exhibited could only be due to purulent effusion in the pleural cavity. Two days previous to Dr. Mullhall's consultation I introduced a needle in the seventh intercostal space a little in front of the axillary line, drawing only a small quantity of apparently sero-purulent fluid. In order to allay the unmanageable struggles of the child a few whiffs of chloroform were administered, but this was soon abandoned on account of alarming symptoms of heart-failure setting in. No further attempts at tapping were made that day. Two days later, with Drs. Mullhall and Ostertag present two more punctures were made with the same result. As the needle was perfectly movable in the mass, it was thought the contents of the chest were too thick to pass through the needle, and while considering for a moment the propriety of making an incision the child suddenly became cyanotic, struggled for breath, and in less than a quarter of an hour expired, all efforts at resuscitation proving fruitless.

Post-mortem twenty-four hours later. On opening the thorax the heart was found pushed over to the right side beyond the right margin of the sternum; the pericardium contained a small quantity of serum. The entire thoracic cavity of the left side was occupied by a white, moderately soft mass, in which no distinct lung-structure could be seen. The left bronchus was entirely obliterated. The heart, the right lung, the spleen and liver showed no sign of disease or secondary degeneration. The neighboring lymphatic glands were

not enlarged nor otherwise diseased. The tumor was easily removed, as there were no adhesions except a cord-like pedicle about the size of a little finger at the root of the lung, containing the blood-vessels that nourished the tumor. The tumor weighed 3 lbs., $3\frac{1}{2}$ ozs., was $6\frac{1}{2}$ inches long, 7 inches broad and $16\frac{1}{2}$ inches in circumference.

Dr. L. Bremer, of this city, to whom the tumor was sent for microscopical examination, made the following report: The tumor is oval-shaped, has the size and form of a human brain minus the cerebellum. A longitudinal median incision makes the resemblance to the two hemispheres a very close one. Its color and consistence is that of brain substance, thus resembling, on coarse inspection, the class of tumors termed encephaloid. Minute examination with the microscope, however, shows that, though a malignant tumor, it is not an encephaloid, if by this name the soft and rapidly growing variety of carcinoma is understood. The surface of the tumor is uneven, recalling the convolutions and depressions of a brain. Sections of its substance reveal in some places a homogeneous white substance; in others it looks marbled, owing to many hæmorrhages which have taken place. These hæmorrhages have also caused many more or less circumscribed softened spots throughout the tumor. An enveloping mass varying between $\frac{1}{2}$ and 1 line in thickness, and of apparently denser consistence, surrounds the tumor and corresponds to the visceral layer of the pleura.

Thin sections of the tumor examined under the microscope show circular and spindle-shaped bodies of considerable size, besides fat globules of variable diameter. Stained with borax carmine and examined in glycerine the spindle cells become more manifest, and it is now clear that the object under examination is a large spindle-celled sarcoma undergoing fatty degeneration. A specimen stained in the same manner but examined after dehydration, in oil of cloves and Canada balsam exhibits large oblong and round nuclei (the latter being the transverse sections of the former) with very little more or less homogeneous or slightly fibrillar basis substance.

Primary spindle-celled sarcomata of the lungs, it seems, are very rare. Other varieties, as carcinomata, adenomata, fibromata, osteomata, and enchondromata, seem to be of somewhat more frequent occurrence as primary tumors of this organ. As a rule, all tumors of the lung are secondary growths. J. S. Billings, Surg. U. S. A., in charge of Library of the Surg.-General's office, Washington, D. C., says: "The only distinctly recognized primary spindle-celled sarcoma of the lung of which I have any note, is that reported by Chiari in the *Wiener Medicinische Presse*, 1878, vol. xix, p. 112. In the 'Transactions of the Pathological Society of London,' vol. ix, 1858, p. 31, Dr. Wilks reports a case of primary tumor of

the lung composed of long nucleated fibres lying side by side, which was probably of the same character. Also in the *Revue Médicale de l'Est*, vol. iv, 1875, p. 119, Dr. E. Demange reports a case of primitive sarcoma of the lung with thrombosis of the pulmonary artery. The tissue of the tumor is composed of fusiform cells with long prolongations, forming what he calls a fasciculated sarcoma, which I take to be the same thing as the spindle-celled sarcoma."

The best authenticated case of primary sarcoma of the lung is that of Dr. L. Ruetimeyer, published in the *Schweitzer Aerztl. Correspond. Blatt.*, 1886, No. 7. He too had mistaken the condition for empyema, and it was the dry tapping that led him to suspect a tumor. Only the lower lobe of the left lung, however, was changed into a sarcomatous mass.

To distinguish such tumors of the lung from empyema, for which it seems they are universally mistaken, there is, I believe, no certain sign, except that elicited by the exploring needle, which must, however, not be too small, and must be inserted at various points in the intercostal spaces, and to a considerable depth. The exuding fluid should be subjected to a microscopic examination, which may possibly reveal the nature of the disease. In my case, owing to an accident, a microscopic examination was not made. The diagnosis in these cases may furthermore be facilitated by considering the peculiarly even distension of the thorax, barrel-shaped; the stretched but not bulging intercostal spaces; the passive dilatation of the superficial veins on the affected side; the greater resistance felt by the finger on percussion; and the total absence of respiratory sounds on the affected side.

ON THE MANAGEMENT OF FUNCTIONAL DISORDERS OF THE STOMACH.

Read before the Georgia State Medical Association, at Macon, Ga., April 19, 1886.

BY P. R. CORTELYOU, A.M., M.D.,
OF MARIETTA, GA.

In calling the attention of this Association for a short time to some points "On the Management of Functional Disorders of the Stomach," I am fully aware that the subject is trite, and that nothing especially new can be said in regard to it. That it has been thoroughly written on by able and scholarly minds, and that in a manner so fully that it would be hard indeed to add even a few threads of purely original thought. My apology, if one be necessary, must be found in this—that it is not the rare and infrequent diseases that most often perplex the daily practitioner, but the more common maladies of every day life, and those which often are considered to be of little special interest;

yet it is often in these very cases that our patients expect and look for speedy relief.

It is not my purpose, nor is it necessary at this time that we should discuss the physiology of gastric digestion, nor the importance of its proper performance, for the securing of good health. Suffice it to say that the stomach is one of the most important, as well as perhaps the most abused organ in the human system. Some ancient solon has said, "Keep the head cool, the feet warm, and the stomach all right, and you will have little need of doctors." However that may be, we know that the condition of the stomach is at the foundation of many diseases.

When we consider what the human stomach has to endure, in receiving into it things hot and cold, raw, boiled, fried, and at all times and hours, from early morn often until the midnight hour, we cannot wonder that it will fail at times to do the work placed upon it.

We are told that Samson, with the jaw-bone of an ass, slew a thousand men, but we think that the hot biscuit and frying pan have slain their tens of thousands.

Among the causes affecting the digestion may be mentioned predisposing and exciting causes. Everything which causes depressed vitality is a predisposing cause to indigestion. It may be caused by hot and debilitating climate, changes in the elementary constituents of the blood, exhausting diseases, mental and moral emotions act as predisposing causes. Age, also, in the extremes of old age and infancy. Anemia, and deficiency of the gastric juice, are also predisposing causes. The immediate exciting causes are errors in diet, excessive eating and drinking. The use of unwholesome food and such as is not properly prepared. Too frequent introduction of food into the stomach without giving the organ sufficient time for rest, acts as an exciting cause. Also irregularity in eating, and rapid eating, the food not being thoroughly masticated.

In treating these cases all these things must be considered and overcome to effect a cure. In the following reported cases, which have been under my care during the past year, I have adopted a somewhat routine line of treatment, but one that has proven very beneficial, and therefore I report them at this time.

Case 1.—Miss H., single, æt. 35 years. I was called to see the patient October 3, 1887. She gave me the following history. She had been suffering for months with severe pain in the stomach, and severe vomiting, often unable to sleep at night on account of the pain. She had lost a good deal of flesh, and was unable to sit up all day. Could eat no solid food without having pain and distress. There was marked tenderness over the epigastrium. The patient very despondent and apprehensive of cancer. Had used various remedies without receiving benefit. Or-

dered glass of hot water to be taken one hour before each meal, and pill consisting of arsenious acid $\frac{1}{6}$ grain, extract nux vomica $\frac{1}{6}$ grain, belladonna $\frac{1}{6}$ grain, reduced iron 1 grain, to be taken after each meal. Blister, size of silver dollar, over the epigastrium, and powder of ingluvin 10 grains, before each meal. Diet, milk, some beef essence, boiled rice. October 6. Patient improving, less pain after eating, sleeps better at night. Ordered bismuth subnit. 4 grains, pulv. pepsin 4 grains, pulv. ipecac grain $\frac{1}{2}$, before each meal, in place of ingluvin. The pills and hot water continued. October 10. Patient still improving. Bowels costive. Ordered fld, ext, cascara sag. 20 to 30 drops at night. I increased diet, giving stale, light bread, crackers, soft boiled egg. Patient able to get out of doors when pleasant. From this date she steadily improved, until she fully regained her strength and was able to take regular diet, her friends telling her she had not looked so well for years, and she still continues to keep well.

Case 2.—Judge C., æt. 71. Called to see the patient April 22, 1888. Gave following history: He had suffered from chronic bronchial trouble for years, and has been spending the winters in Georgia and Florida. He had just come from Florida and was suffering with severe cough, just recovering from an acute attack of bronchitis. His stomach was very tender on pressure, and he was unable to take food without pain and distress, and nausea. Ordered quieting mixture for the cough. Glass of hot water one hour before each meal, with elix. lactopeptine after each meal, and small blister over the epigastrium. Diet: milk, beef essence, crackers, and stale bread. Patient improved rapidly under this treatment, the hot water having a very beneficial effect on his stomach. In about ten days he was able to take regular diet with appetite and without distress.

Case 3.—Miss B., æt. 40. Called to see patient July 1, 1888. She gave following history: For several weeks had been suffering with severe pain and distress on taking food, and with severe choking spells, Complaints of burning and boring pains in the stomach, and tenderness on pressure. Much emaciated, unable to sleep, pale and nervous, anæmic and despondent. Had been under treatment, but received no benefit. Ordered glass of hot water one hour before each meal, small blister over the epigastrium, and powder of bismuth and pepsin, 5 grains each, after meals; aromat. spts. of ammonia, Hoffman's anodyne, and spts. lavender Co., for choking spells. Diet: milk and lime water, stale bread and some chicken broth. July 9th. Patient improving, but still complains of pain in the stomach, but not so constant. Ordered powder of $\frac{1}{4}$ gr. calomel, $\frac{1}{15}$ gr. morph. sulph., 5 grains bismuth subnit, after each meal. Patient improved steadily on this treatment with the hot water; increased diet, giving soft boiled

eggs, soft boiled rice, tea, soda crackers. July 31, 1888. Patient gaining in strength and color and flesh, has very little pain after eating. Ordered pill of $\frac{1}{30}$ grain arsenious acid, $\frac{1}{8}$ grain ext. nux vomica, and 1 grain each of quinine and reduced iron, after each meal. From this date patient steadily improved, and returned to her regular diet, and had no further trouble.

Case 4.—Mrs. M., colored, æt. 35. I was consulted by patient July 31, 1888. She gave the following history: Had been for weeks suffering with severe pain in stomach and left side; unable to take food without pain. Had been under treatment, but received no benefit. Ordered glass of hot water one hour before each meal, fly blister over stomach, powder of bismuth and pepsin, 4 grains each, after meals. Diet: milk and line water, stale bread, and soft boiled rice. Patient improved rapidly on this line of treatment. August 9th. Patient able to take food without pain or distress. Ordered mixture of nux vomica, bismuth and carbolic acid, after each meal, and from this time she has had no further need of treatment.

Case 5.—Mr. A., æt. 35, married. Called to see patient November 29, 1888. He gave the following history: For about one year had been suffering from severe attacks of pain in stomach and bowels, which unfitted him from attending to his business, and frequently prevented sleep. Had lost considerable flesh and was very despondent. Had been under various lines of treatment, but received no permanent relief. His skin was sallow, tongue coated with white fur, bowels costive, tenderness over the epigastrium and liver. Ordered glass of hot water one hour before each meal, small blister over the epigastrium, mild laxative for constipation, and mixture of acid nitro hydrochl., dil., 5iss, syr. sarsaparilla co. 3ij; one teaspoonful to be taken after each meal. Diet: milk and lime water, beef essence, stale bread and soft boiled rice. On this line of treatment patient continued to improve and was relieved of pain and distress, gradually became able to take fuller diet, and gained in strength and flesh. April 1, 1889. The patient has been at work during the winter, has gained 15 pounds in flesh and able to take his regular meals without trouble, but still using the hot water once a day and the nitro. hydchl. pil. occasionally.

From the results obtained in these cases, with others not reported, I have been led to feel that in hot water, properly used, we have a very beneficial agent in all catarrhal conditions of the stomach, and one that is generally grateful to the patient. I have also found the use of small fly blister over the stomach to aid in relieving nausea and pain and tenderness, and think that these means, together with proper regulation of diet, will be successful in relieving many of these distressing and troublesome disorders of the stomach, which are functional.

UNCOMPLETED NEPHRECTOMY.

CALCAREOUS VESSEL MISTAKEN FOR A CALCULUS BY THE NEEDLE TEST—OPERATION ABANDONED ON ACCOUNT OF ADHESIONS—DEATH—AUTOPSY—PRIMARY EX-CEPHALOID OF THE KIDNEY.

Read at the Regular Meeting of the Philadelphia County Medical Society, March 27, 1889.

BY W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PHILADELPHIA

G. M. C., æt. 68, weight 164 pounds, 6 feet 2 inches tall, was sent to me through the kindness of Dr. E. W. Watson, on October 31, 1888, with the following history:

On April 6, 1886, he had an attack of retention of urine. Violent expulsive efforts forced out a clot. The bleeding continued two or three days. With this he had pain in the right lumbar region. A month later another similar attack occurred, the pain on this occasion being quite severe and amounting to a distinct renal colic. Other attacks, always accompanied by pain and bleeding, occurred in July, 1886, and in January, September and November, 1887. After the last one, for several weeks he had repeated and nearly continuous hæmaturia with a sensation of heat in the right lumbar region, and he lost strength and appetite.

January 14, 1888, he was taken extremely ill with pleuro-pneumonia and septicæmia. Both legs were attacked with phlegmasia. The dullness in the right kidney, Dr. Watson stated, was increased, but no pus was found in the urine either then or at any other time; neither were any symptoms located in the bladder. This illness lasted about two months.

In May and June of 1888 he again had attacks of hæmaturia, and from September 17 to October 31, 1888, he has had nine attacks, passing as much as six or eight ounces of blood, he thinks, in some of the attacks. He has never passed any calculus. In the interval between the attacks the urine was clear. No cause can be assigned for the attacks; not uncommonly they have come on while he was lying in bed. He states that the right kidney is now the seat of marked aching pain.

Present condition.—He is a very tall man with a disproportionately long chest; from the ribs to the crest of the ilium the space is barely two fingers in breadth. The bladder was sounded but no stone was found. Its walls were rugose. The prostate not much, if at all, enlarged. Renal dullness on the two sides equal and normal. Right kidney tender. Two specimens of urine were furnished, one with a large bloody sediment, but without clots, and the other clear and acid, sp. gr. 1022; very slight amount of albumin. Microscopic examination showed no crystalline elements, a few blood discs, granular matter, and a large number of bright fatty-like small globules. Dr. Watson informed me that he had never

found any albumin except just after the attacks of hæmaturia, nor has he ever seen any cast.

It was decided to explore the right kidney, either for stone or possibly for cancer, and either to remove the stone or the kidney, as might seem best.

Operation, Nov. 3, 1888.—Present, Drs. E. W. Watson, A. W. Watson, W. J. Taylor, and T. R. Neilson. An oblique incision, four inches in length, was made just to the right of the erector spinæ, and the perinephritic fat was reached. Surrounding the kidney was a capsule so loose and distinct that it required a very careful examination to be sure that it was not the wall of the colon. The lower end of the kidney appeared normal. The finger detected a rather sharp irregularity deep in the substance of the kidney. The moment it was pressed on, both Drs. Taylor and Neilson, as well as myself, were convinced that it was a stone. A needle was then passed into the kidney, and the point of it grated with great distinctness against the supposed stone. The kidney was now seized with a volsella, and was loosened from the surrounding tissues in order to obtain freer access to it. This was followed by two results: First, very abundant, indeed very alarming hæmorrhage, from large veins that were so concealed under the last rib that they were seized with great difficulty, even after the rib was well raised, and when seized they were so friable that the ligatures would not hold.

The second result of this operation was to disclose the fact that while the small portion of the kidney first discovered was normal, the rest of it was irregular, nodular, and friable, and evidently the seat of a malignant growth. Accordingly, I determined to remove the kidney, if possible. It was rapidly detached from its capsule by the finger, but it was so anchored internally at the hilum that it could not be brought to the surface, in spite of the fact that I got my entire hand into the cavity of the capsule.

Having proved the impossibility of removing the kidney by the loin, I debated the question of attempting it by an anterior incision, but as the difficulty of removal was not the size of the kidney, but the adhesions at the hilum, I concluded not to attempt an operation by this route, as I felt convinced it would result in the patient's dying upon the table. The hæmorrhage had been exceedingly profuse, not from any one particular vessel, or from rupture of the vessels of the hilum, but from every point in the kidney and in the capsule the moment they were separated. This hæmorrhage was checked by thoroughly packing the wound with sublimate gauze. The patient was put to bed. He became conscious and recognized his family, but died from exhaustion three and a half hours after the operation.

Autopsy, twenty hours after death. In order

to determine whether I could have removed the kidney more readily by the anterior incision, I made this attempt as the first step in the autopsy. An incision was made in the right linea semi-lunaris. This incision measured four inches in length, extending from the border of the ribs to Poupart's ligament. No more room, therefore, was obtained for the removal of the kidney anteriorly than posteriorly. The ribs projected so far downward that, in order to reach the kidney, it was necessary to insert my entire hand up to the wrist. The kidney lay far up under cover of the ribs, and was as inaccessible from the front as from the back. It was so thoroughly anchored in its position that to loosen it from its bed required force that would have been wholly unjustifiable during an operation, and would have resulted in rupture of the vessels and in immediately fatal hæmorrhage. It would not have been possible to reach and tie the vessels in such an inaccessible position. When removed, the kidney was found to be enlarged, nodular, and distinctly cancerous. The left kidney and other abdominal viscera were normal.

On section of the kidney there were discovered some calcareous vessels and one or two points of calcification of the other tissues. The kidney measured seven and a quarter inches in length, four and three-quarter inches in width, and three and one-quarter inches in thickness.

Microscopical examination by Dr. J. P. Crozer Griffith showed that it was an intermediate form between scirrhus and encephaloid, with a decided preponderance in the greater part of the organ of the latter form of the disease.

REMARKS—*First, diagnosis*.—This lay most likely between stone in the kidney and cancer of the kidney. Although it seemed unlikely that stone should exist without producing pyelitis and, therefore, showing some pus in the urine, yet I have known of more than one case of both stone in the bladder and in the kidney in which the urine contained no pus. The repeated hæmaturia looked very much toward malignant disease, but the kidney was so under shelter of the ribs that it was impossible to detect any tumor, and the dulness was not markedly increased. The enlargement of the kidney was chiefly toward the hilum, and so the dulness posteriorly was little greater than normal. Mr. Henry Morris states that of thirty cases of cancer of the kidney, found in 2,610 autopsies, twenty-five were secondary and only five were primary. The present specimen is undoubtedly a primary malignant tumor, and is, therefore, a rare form of disease.

Secondly, the surgical aspect of the case.—In this there are two points of interest: First, the needle test for stone. When the kidney was exposed to view, the only healthy portion of it remaining was first seen. Deep under this an irregular, hard mass could be felt, which might easily be a

stone. Puncture by the needle convinced us that it was such. Examination of the kidney after death showed us that no stone existed, but that what was felt by the point of the needle was either a calcareous vessel or a calcareous degenerative mass against which the point of the needle grated. It gave precisely the same sensation as a stone would have done. This possible error seems to me very unusual. I have never seen it noticed, although it may have escaped my knowledge.

Secondly, the advantages of the lumbar or of the abdominal route for removal. As the operation was undertaken primarily for exploration, and no tumor in any sense was discovered, I am clearly of opinion that the lumbar route was the proper one to select. The attempt made at the autopsy shows that the kidney could not have been removed any more readily by the abdominal than by the lumbar incision. The peculiar situation of the mass in question, and the low position of the ribs, resulted in the curious fact that while the space between the last rib and the crest of the ilium was only two fingers in breadth, yet the oblique incision here of four inches was long enough for removal, and it could have been still further prolonged anteriorly if necessary; whereas, the vertical incision from the rib to Poupart's ligament was absolutely limited to four inches, and the kidney was certainly no more accessible by this route than by the other. The removal of the kidney was practically impossible by either method. The inflammatory attachments—especially around the hilum and the great vessels of the kidney—required an amount of force that would have been unjustifiable during life.

LIGATION OF SPLENIC ARTERY FOR CURE OF HYPERTROPHY OF SPLEEN.

A Paper read before the Wayne County Medical Society, May 2, 1889.

BY HAL C. WYMAN, M.D.,

PROFESSOR OF PRINCIPLES OF SURGERY, MICHIGAN COLLEGE OF MEDICINE AND SURGERY, DETROIT.

An Italian, æt. 45 years, who had lived in America and the valley of the great lakes for five years, was brought to the Emergency Hospital with a tumor occupying the left abdominal cavity. His history showed that he had had repeated attacks of malarial fever, which had been treated with quinine. Three years ago he first noticed the tumor in the abdomen, and found himself growing weaker than the previous attacks of ague accounted for. For about a year he had been unable to work owing to the shortness of breath caused by the pressure of the tumor on the diaphragm. He had been constantly under medical care. Had had mercurial and iodine ointments rubbed over the tumor, had taken med-

ical treatment from quacks as well as regulars, but steadily grown worse. He solicited an operation. I examined some of his blood taken from his gums, and could detect no want of proper relation existing between the white and red corpuscles.

I made a careful surgical survey of his case. Found the tumor an enlarged spleen, the hilum of which could be felt as a notch 1 inch to the right and below the umbilicus. His skin was tawny but natural in color. His urine was normal. His stools were infrequent, very hard and dry. His heart and respiration normal, so far as physical signs were able to detect their functions. The lymphatics were not enlarged.

The tumor was immovable, adherent apparently to the abdominal parietes beneath the ribs and along the left side. He said his strength was steadily failing, that he could not breathe much longer unless the tumor was taken away. I determined to operate. I had little hope of removing the spleen, so firm were its adhesions, but I hoped to bring about its atrophy by starving it. In the presence of the students of the Michigan College of Medicine and Surgery, and a number of professional friends, I opened the abdomen in the linea alba. The wound oozed freely, but hot water sponging checked it. The omentum was found very adherent. The spleen was adherent to a part of the intestine, omentum and abdominal wall. Carefully I made my way to the hilum of the spleen and, isolating two branches of the splenic artery as they entered the organ, ligated them with carbolized silk. Some hæmorrhage ensued, but hot sponges checked it. The abdominal wound was closed and dressed antiseptically. The patient suffered greatly from shock, but rallied after about twelve hours. Twenty-four hours after the operation he began to vomit and his temperature rose to 104°, with small pulse. Vomiting soon became severe, and collapse, preceded by acute peritonitis, closed the scene forty-eight hours after the operation. No autopsy was permitted, but the tumor shrunk remarkably as a result of the ligation of the arteries. I was led to perform this operation as a result of a series of surgical studies of the consequences of ligation of the splenic artery and its branches in dogs. Ligation of the common splenic artery of the dog was followed by death, and the autopsy showed an acute necrosis of the spleen. Ligation of two branches of the artery which supply blood to about one-third of the spleen caused, in most instances, a progressive atrophy of that part of the spleen deprived of its arterial blood. The dead spleen pulp, when injected beneath the skin of rabbits, caused death after twenty-four hours with symptoms of acute sepsis, suggesting the idea that the spleen is a place for the physiological metamorphosis of septic materials, and that the organ enlarges after malarial poisoning in the

endeavor to perform its functions. The other ductless glands may assist in this labor, and be able to perform the functions of the spleen when that organ is overworked or has been removed from the system.

REPORTS FROM HOSPITALS.

SURGICAL CLINICS AT THE WESTERN PENNSYLVANIA HOSPITAL BEFORE THE STUDENTS OF THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

BY PROFESSOR J. B. MURDOCH.

SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL AND PROFESSOR OF CLINICAL SURGERY IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

[Reported by WILL. N. PRINGLE, M.D., a member of the Graduating Class.]

December 8, 1888.

OPERATION ON A CRUSHED HAND.

The case which we will show you first to-day is one of those very frequent accidents that we see, namely, a railroad crush. This young man was following his occupation as a railroad brakeman, last Sunday, six days ago, when he had his hand crushed in the terrible manner which you see. He was brought here, but he stontly objected to an amputation, and his father, who was with him, also refused to give his consent to an operation. He has, however, seen the error of his way, and now wants an operation done, and an operation that should have been done six days ago will be done now.

Amputations are divided into three periods in regard to the time of their performance, namely: the primary, the secondary, and the intermediate. In cases where a limb is hopelessly lost, all authorities now agree that the sooner it is removed the better. In these cases, in this institution, we operate at once, just as soon as the patient comes under our care; provided, of course, that he is not in profound shock, and not actually dying. And, by carefully examining the statistics of the hospital for the last twenty years, we find that the mortality is wonderfully decreased by so doing. And just here let me say, that the comparison of the records of other hospitals with the records of this hospital shows that more amputations are done here, than are done in any other hospital in the United States; and further, that, according to the number of patients treated, more amputations are done in the Western Pennsylvania Hospital than are done in any other hospital in the world. This statement is the result of careful researches and examination of records and statistics of this and other countries.

Now, in cases of accidents, the question you

will often be called upon to decide will be, "Is amputation required or not?" While we try to practice conservative surgery here, and try to teach you conservative surgery, we desire to teach you that *intelligent* or *practical* conservatism which is such a priceless boon to him who possesses it. To illustrate, you see the middle finger of this crushed hand. Although the bones are not broken, the soft parts are contused and lacerated almost its entire length. One kind of conservatism might save that finger. The man would be compelled to remain in the hospital for six weeks, then carry it in a sling for six months, and at the end of that time have a stiff, crooked, useless member, which would continually interfere with the performance of his duty, and perhaps in one year he would come back that we might remove the unsightly, useless member. This is not the conservatism that we would teach you. A member that is preserved merely to hang to the body of the patient as a useless, unsightly encumbrance, and to interfere continually with the proper performance of his duties, or station in life, does not exhibit the practice of true conservative surgery. I will remove the index and middle fingers of this hand at the metacarpo-phalangeal articulation, and in order to get skin enough to make good flaps, will saw off the head of the metacarpal bones. This will leave the man a reasonably useful hand, because he has his thumb remaining, as well as his fourth and fifth fingers. I think that the loss of a thumb is almost equivalent to the loss of a leg, because the remaining fingers having no opponent, are thereby rendered almost useless also. This hand will be dressed in the usual manner, with antiseptic dressing, and we may bring him before you again.

EXCISION OF THE METATARSAL BONE.

We have another case here which will serve as an example, and a warning in regard to the care of the feet. This old gentleman is an Irishman 65 years old, a daily laborer, and resides in that odorous as well as historic locality known as "The Point," and within a short distance of old Fort Duquesne. He was a gay young man at one time, fond of dancing and of wearing tight shoes; and as a result we see such a deformity of his feet as it is but rarely our privilege to behold. His great toe lies almost transversely across the second and third toes, and these, together with the fourth toe, are all dislocated at their metatarso-phalangeal articulation. The elastic spring of the foot is lost, and he walks on the base of the phalanges, over the site of which bunions have formed, which have become so painful that he can only walk with great pain and difficulty. In buying a shoe, the sole should be at least as wide as that of the foot. It seems that people will subject their feet to more pain and agony, for sweet vanity's sake, than they will any other part of

their bodies. It is no rare thing to see women especially with narrow heels on their shoes, 2 inches high, not under the heel of their foot, but under the middle of their foot, and their toes all cramped down into the point of a narrow shoe, causing corns, bunions, warts and deformities, and not unfrequently dislocating the tendon of the tibialis posticus muscle where it passes behind the malleolus; and not only all of these, but the general health suffers, because they who cannot walk cannot take that exercise so conducive to perfect health.

In recent deformities of this kind, or where the deformity is not great, no operation is required. In these cases Dr. Lewis A. Sayre puts a rubber stall over the toe, and to this attaches a strong piece of elastic rubber, and to this fastens a strip of adhesive plaster. The toe is then brought into line, and the plaster fastened to the heel, thus, through the elastic, keeping up a steady traction on the toe.

Now, we propose to do something to relieve this gay Lothario, and but one choice is left us, namely: excision of the metatarsal bone. There are two ways of doing this, however. One way is to open the joint and excise the head of the bone; the other way is to remove a piece from the shaft of the bone below the joint. I propose to open the joint and excise the head of the bone. There are two incisions that may be made here, a straight or an oval, but, as I think I can expose the head of the bone with considerable ease, I will make a straight incision. After the head of the metatarsal bone is removed and the toe brought into position, the base of the phalanx and the sawn surface of the metatarsal bone will be held in close apposition by wires passed through both bones. I will also excise the head of the second, third and fourth metatarsal bones. By a little attention the foot may now be made to present a reasonably good appearance. It will be retained in as good a position as possible by bandages, and in a few weeks this man will have less distress in walking, although he may still not have a perfect foot.

December 22, 1888.

I will show you first to-day the case in which we excised the head of the metatarsal bones of the first, second and fourth toes, two weeks ago. You remember the great toe lay directly across the ends of the second and third toes, and that the toes were all dislocated at their metatarsophalangeal articulations. You see now that the toes all present a reasonably good appearance, and that the great toe is in a line with the inner border of the foot, as it should be. The original dressing put on this foot was not disturbed till the end of ten days, when it was removed and the condition you see here was presented. There is still a wire suture remaining in the wound, but if the wire does not disturb the man we will not disturb the wire.

OPERATION FOR TUMOR ON THE FACE.

The next case is one of tumor occupying the side of the face, or overlying the parotid gland. This man says that it has been growing for twenty years, but that ten years ago it was removed or partly so, but that it began to grow again, and has continued to increase slowly ever since. You can see the cicatrix where it was opened before. Now, the growths that may occur in this locality are various, as enlarged lymphatic glands, enlarged parotid gland, encysted tumor in the parotid gland—and this latter is what I believe this to be. If this is the case I will not likely be able to remove it whole, as it will likely rupture or tear, and the contents be evacuated. In that case I will make an effort to remove the sac by cutting, dissecting or tearing it out. If I am unable to do this I will simply cut off the outer portion, insert a drainage-tube, and sew it up. In removing tumors it is always well to make a free incision through the skin, in order to give yourself plenty of room, then cut down carefully until you find the capsule and cut through it; however, as I do that in this case, the sac is torn and the contents which consist of a large amount of colored blood plasma. I find that the sac is very intimately attached to the surrounding structures, and that the parotid gland is involved in the mischief. If it were not for the long standing of this growth I would look upon it with suspicion, and as it is I am not satisfied that it is not a malignant growth. We will wash the cavity out with bichloride solution and provide free drainage, and make an effort to convert it into an abscess and prevent its return provided it is not malignant.

It is very unsatisfactory to begin an operation and not be able to finish it. You should never begin an operation with so much determination that you cannot stop, when you find that it is to your patient's detriment that you go any further. This is frequently done by surgeons, especially in laparotomies. They open the abdomen expecting to find a certain tumor, or condition, and failing to find what they expected, they cut, and probe, and search for what they wish to find, until they do irreparable injury to their patients. Always be prepared to end an operation when you find that you can do no more good, however unsatisfactory it may be.

FRACTURE OF THE TIBIA AND FIBULA.

We have here another case, a man with a fracture of the tibia and fibula, at their lower third. You see we have all of the symptoms of fracture here. Now this was done by direct violence (this man was struck with a stone) and is much more dangerous than if it had been done in jumping from a height, or any other indirect violence. It requires a much longer time to heal. We had a man in the wards here last summer, who was struck with a brick, and it was six months before

it healed. In cases like this, where there is so little swelling and tumefaction, it has been our practice to incase the limb in a plaster dressing at once, but it has been my fortune to see a good many cases of delayed union follow this practice, so I am beginning to look on it with suspicion. It may be that a sufficient amount of blood is not sent to the part under a plaster dressing, or that this dressing in some other way interferes with perfect union. I am, therefore, inclined to try the other way for awhile in cases of fractured leg from direct violence, or until the same bad results convinces me that the early dressing in plaster is not in some way responsible for the delayed union. This limb will, therefore, not be dressed in plaster for four or five days more. It is now two days since the accident occurred.

OPERATION FOR INJURY TO THE FOOT.

Another case is that of a boy who six months ago fell from a hay-loft, injuring his foot. The leg and knee soon became swollen, and when the swelling subsided the numerous openings you see appeared over the front part of the leg. These openings have a pouting appearance, peculiar to themselves, and they are called "cloacae," from their fancied resemblance to the anus of the hen, they always lead down to dead bone. As I pass the probe down I come in contact with dead bone at once. You will also notice another defect in this leg, namely, that it is bowed outward. This is caused by the fact that part of the tibia has been lost through necrosis, and the entire weight coming on the fibula, it has given way, or bent from the pressure, causing the bowing of the leg. Now we propose to cut down on the tibia and remove the necrosed bone, and in order to cause the sole of the foot to set flat on the floor we will fracture the fibula, and allow the fragments to overlap each other to a small extent, thus reducing the length of the fibula to that of the tibia. I will make an incision, clear down on to the bone, then with a periosteum elevator, lift up and preserve the periosteum. You see that the tibia is separated at its epiphysis above the ankle, and with very little force I am able to remove a sequestrum about 8 inches long, and almost a perfect mold of the tibia, except where it has been destroyed by the disease. It is the most perfect specimen of sequestrum that I have ever removed from so small a limb. I will pack the cavity with iodoform gauze, and leave the lower one-third of the wound open for the purpose of drainage. The boy, I think, will have a reasonably good limb, although amputation of the limb was at one time considered necessary.

EXTIRPATION OF AN EYEBALL.

January 5, 1889.

I have a patient to-day for whom I will extir-

pate an eyeball. This, properly, should be done by the ophthalmologist, but as this is an operation which you may all be called upon to perform in your practice, I thought proper to bring the case before you to-day. Besides, if all the accidents to the eyes are given to the oculist, and the gynecologist does all the operations falling within his line, and the genito-urinary specialist is given all cases peculiar to his practice, and all the other specialists get their share, there will be but little left for the general surgeon. I, myself, am a specialist, and my specialty is, as Mr. Wilson once said, the skin, and all it contains. When the eye is hopelessly destroyed it should be removed. Because, in the first place, an artificial eye may be better worn, and in the second place, the inflammation and the pathological changes which are set up, are capable, by sympathetic action, of destroying the sound eye. And although the inflammation may be subdued for the time being, and the useless member allowed to remain, still at any time, and from slight provocation, a new inflammation may be set up and the sound eye be quickly destroyed. This man was struck in the eye by a piece of steel, six years ago, and had his eye destroyed. It did not, however, give him much trouble until within a few days, when a new inflammation attacked it, and which is now slowly invading the other eye. The man has applied to us for relief, and extirpation has been decided upon. In doing this the wire speculum is inserted to hold the lids apart. The conjunctiva is then picked up with a small forcep and cut clear around, near the cornea. The recti muscles are then all divided, as close to the sclerotic as possible, and the eye will then bulge forward. You then use a pair of curved scissors to cut off the optic nerve. Of course, when about to do the operation, you will be careful about the eye you are going to remove. Surgeons have been known to remove the wrong eye. This would be a great mistake. After the recti muscles are all divided you introduce the scissors, closed, and feel for the optic nerve. I prefer to introduce the scissors on the nasal side, as the nerve is nearer that than the other side. When you have found the nerve the scissors are opened sufficiently to grasp the nerve and snip it off, as I do here. After the nerve is divided the oblique muscles still remain, which I will divide close to the sclerotic, when the globe is removed with ease. The eye should, where possible, be removed before the humors are allowed to escape, as it is done with less facility when emptied of its fluid. If there is any bleeding in the wound a little water usually controls it, if not, then a cotton compress held in the socket by a bandage is sufficient to control any hæmorrhage there is likely to be. In about three or four weeks this man can be fitted with an artificial eye. He will for the present be kept quiet and his eye kept bandaged.

AMPUTATION OF THE LEG.

We will next show you a boy for whom I amputated a leg just twenty-four hours ago. There has been some rise of temperature, and some soiling of the dressings, so I will take the dressing down and ascertain, if possible, the cause of this disturbance. As I inserted a rather large drainage tube I will now remove it. I think that by this time the serum is all drained from the wound, so that it will not suffer by the removal of the tube. The wound will then be redressed and not disturbed for two, three, or perhaps for four weeks, unless another rise in temperature should indicate that all is not going on well. A large amount of dressing should be placed over wounds like this, so as to absorb all the fluids that may come from the wound, because the moment that the blood shows itself on the outside of the dressings the danger to septic infection at once begins, as the germs more easily penetrate the dressing. It is for this purpose that we use such large amounts of absorbent cotton. And in regard to bandages let me say here, that the ordinary crinoline bandages are the best for wounds like this. When applied wet they adapt themselves nicely to all inequalities of the surface and when they afterward become dry the sizing which is contained in their meshes acts in a modified degree like the plaster in a plaster dressing, making a firm and altogether very excellent dressing. For fractures where you wish to hold parts in apposition, or where you wish to retain splints, or make pressure, the ordinary unbleached muslin makes better bandages. This wound will now be redressed, antiseptically, much the same as an original wound, with the exception of a drainage-tube, and we anticipate no more trouble from it.

MEDICAL PROGRESS.

ACUTE GENERAL ŒDEMA OF THE LUNGS.—DR. M. GROSSMANN has made a number of experiments supplementary to a work previously published on "Muscarin-Œdema of the Lungs." Recent investigations treat the subject of acute general œdema of the lungs on a broader basis, inasmuch as they touch not only muscarin œdema of the lungs but also the acute general œdema, originating from certain other especially mechanical influences. In reference to this it is proven that in the dog—not in the rabbit only, as was supposed—an acute general œdema of the lungs is produced by obturation of the left auricle and by squeezing the left ventricle.

The investigations furthermore extended to the nature of the difficulty in breathing, hitherto unknown, which appears in a lung overfilled with blood which transudes readily. It is proven that

but secondary importance is to be attributed to the transudation itself, and that the principal obstruction to breathing originates from the rigidity of the lung. The supposition that the capillary ecstacy caused by the stopping of the blood produces the obstacle to breathing by diminishing the alveolar space is disproven by the fact that in consequence of the congestion not a diminution but an enlargement of the alveolar space, *i. e.* an enlargement of the lung occurs. The author furthermore mentions experiments which show that transudation artificially produced is not an essential obstacle to breathing, from which he draws the conclusion that no especial significance attaches to transudation as an obstacle to respiration. Supplementary to the theory of muscarin intoxication, his recent experiments show that through this poison not only congestion and œdema but also swelling and rigidity of the lungs and bronchial convulsions are produced.

The author describes the process of acute general œdema of the lungs in this way, that the congestion in the lung, by producing enlargement and rigidity, becomes an obstacle to respiration and causes as a final anatomical result transudation.

The primary cause for congestion of the lungs the author, on the ground of his experiments, finds in a narrowing of space of the left portion of the heart, as opposed to the theory of Cohnheim, Welch, who considered a paralysis of the left side of the heart as the cause of œdema of the lungs.—*Internationale Klinische Rundschau*, 1889, No. 15.

ON THE INFLUENCE OF THE DIFFERENT METHODS OF TREATMENT OF ABDOMINAL TYPHUS IN CHILDREN UPON FLUCTUATIONS OF TEMPERATURE AND BODY-WEIGHT.—DRS. LUMIN O. MEYER, R. PETERS and C. TANNENHÄUSER report a number of cases from the hospital for children of the Prince of Oldenburg, of the years 1875, 76, 77, 84, 85, 86 and 87. Excluded were cases in which the fever lasted only one week, such as originated during the last period, and cases complicated with other diseases. Therapeutic experiments were made—1, with baths of 38° C. to 8 times daily, in temperatures exceeding 30° C.; 2, baths of 33° C. with dashes of 22–18°; 3, 4 to 12 dashes daily; 4, large doses of quinine 0.3 twice or 0.5–1.00 once daily; 5, large doses of quinine simultaneously with antipyrin; 6, antipyrin; 7, quinine an antifebrin; 8, antifebrin; 9, amm. salicylate. To render a comparison possible a series of cases was treated expectatively with acid muriatic. For each individual case the average temperature of 5 to 10 measurements was calculated, and with these figures an ideal curve drawn for each. A comparison of all the curves showed remarkable similarity. All curves descend gradually and in

steps, the temperature reaches its acme on the fourth day, to fall after that, only in the cases observed from the first day of sickness a rapid rise of the temperature was noted in the beginning. The antipyretic methods above mentioned did not alter the temperature curve at all. The weight of the patients was taken from one to seven times a week, the daily loss was figured out in per cent. of the body weight as existing on the day of reception into the hospital; the gain, however, in per cent. of the lowest body weight observed.

Dr. Senetz, of St. Petersburg, declares that the measurement of weight in his cases of abdominal typhus showed that an energetic antipyresis had an effect upon the body weight in so far that its decrease lasted for a longer time, and its increase was slower than with indifferent treatment, that the curve of body weight is one of the most reliable clinical symptoms for judging the course of the disease, and that with an energetic antipyresis the course and convalescence are more protracted; in children from 7 to 8 years old the body weight increases much more quickly and a cure ensues sooner than in adults.—*Internationale Klinische Rundschau*, 1889, No. 15.

RESECTION OF THE ENSIFORM CARTILAGE.—An important paper has recently been presented to the Royal Academy of Medicine and Surgery of Naples by a young surgeon, DR. RINONAPOLI, of Collamele, in the province of Aquila, giving the details of an operation for resection of the ensiform cartilage. Only one such case has been previously recorded—by Linoli, in 1857. A man was injured by a horse rearing and falling back upon him. His chest was violently compressed, and the ensiform cartilage dislocated backwards. The displaced cartilage, by its pressure on the stomach, was productive of very severe gastric disturbance, which at length became so great that not even the smallest quantity of milk could be taken without terrible pain. The patient rapidly wasted away, and his life was despaired of. Various diagnosis were made, but it was left for Dr. Rinonapoli to discover the true state of affairs. Being convinced of the accuracy of his diagnosis, and fortified by the opinions of two colleagues, Dr. Rinonapoli gained the consent of the patient and his friends to an operation.

The minutest antiseptic precautions (carbolic acid and perchloride of mercury) were observed. An incision six centimetres long was made, the upper third being over the sternum. Dissection was carefully carried down to the peritoneum, which was not opened. The cartilage was separated from the structures enveloping it, and, finally, its attachment to the sternum was divided by passing a probe-pointed bistoury behind and cutting forwards. The wound was carefully cleansed and brought together by sutures. In

the course of five weeks the patient had completely recovered. The points of interest connected with the case are: 1. That it is only the second recorded. 2. The peritoneum was not opened. 3. It was undertaken by a young surgeon in a country district in Italy, who, with the assistance of two other country surgeons, carried it through in the most praiseworthy manner. Dr. Rinonapoli worthily won his admission to the Royal Academy of Medicine of Naples, for which Professor Fusci stood his sponsor.—*Lancet*, March 16, 1889.

ON COCAINE—EPILEPSY.—DR. C. HEIMANN, of Charlottenburg, reports in the *Deutsche Medicinische Wochenschrift*, the case of a patient in whom after long subcutaneous use of large doses of cocaine (up to 8.0 daily), besides cocaine-paranoia (repeatedly observed during the past years by the author and others), epileptic convulsions occurred. They closely resembled the classical symptoms of epilepsy, and were accompanied by disturbances of the sensorium, complete numbness, subsequent failure to remember the attack, etc. After stopping the use of the poison the morbid symptoms, hallucinations, perverse sensations, frenzy, etc., disappeared, and the convulsions ceased but recurred always when large doses of that drug was used. Now since no other causative factor for epilepsy existed in the patient, hereditary influences were missing, and convulsive conditions had never before been known to him, the author concludes that in this case epilepsy was caused by the alkaloid. This conclusion is supported by experiments on animals in which epileptic fits also occurred after cocaine.—*Therapeutische Monatshefte*, 1889, No. 4.

ON THE WASHING OF THE ORGANISM IN INTOXICATIONS.—PROF. SANQUIRICO has shown that the fatal consequences of an acute intoxication produced by various substances can be avoided by means of washing the organism as proposed by him and often tested, and that this antitoxic treatment is often more valuable than all other methods used in cases of poisoning. Prof. Sanguirico now describes a modification of his treatment which experimentally has proven perfectly effective. The modification consists in this, that for the poisoned individual he makes use, on the one hand, of the physiological antagonism of a drug capable of fully exerting the latter, and on the other hand of the depurative effect of the washing. With this combined action—which is variously applied in given cases—the author wants to serve a two-fold purpose:

1. To obtain a cure in animals poisoned by a quantity against which either of the two ways alone would be insufficient.

2. To obtain a success also in those cases of poisoning in which the simple washing as well as

also the action of a powerful antidote proved useless.

A long series of tests made by Prof. Sanquirico have established the undoubted efficiency of the combined treatment in cases of acute poisoning. It might, therefore, also be used to advantage in acute intoxications in man.—*Internationale Klinische Rundschau*, 1889, No. 15.

CHLORIDE OF BARIUM IN HEART DISEASE.—According to *Les Nouveaux Remèdes*, H. A. HAZE prescribed the chloride of barium in seven cases of heart disease (once for an infant 6 years old with lesion of the mitral, once for acute dilatation of the heart, twice for lesions of the aorta and once for lesions of the mitral in an adult, and twice for functional disturbances of the heart). The results obtained were very good. In all cases the drug slackens and regulates the heart-beat, augments the amplitude of the pulsations without producing as pronounced a tension as the finger applied to the artery feels after digitalis. At the same time the pulse is considerably prolonged. No renal troubles. The author administered the drug in a 1 per cent. water solution; 1.50 to 2 gr. of this solution repeated three times daily for children, and 5 gr. two or three times daily for adults. In these doses it may be considered as not toxic. As it is, besides, almost tasteless and inexpensive, and acts as rapidly as digitalis, it is to be supposed that this drug will soon render valuable service in the treatment of heart disease.—*Journal de Médecine de Paris*, 1889, vol. xvi, No. 15.

THE TREATMENT OF ACNE.—DR. ISAAC, assistant to Dr. Lassar's clinic for skin diseases in Berlin, discusses in the *Berliner Klinische Wochenschrift*, No. 3, 1889, acne and its treatment. As an etiological factor in the production of acne, he considers that hereditary peculiarities in the opening of the sebaceous glands may have an influence. In such cases the sebaceous duct is wide and funnel-shaped, offering a nidus for dirt and other septic material. Though such anatomical peculiarities may in exceptional instances predispose to acne, its causes are to be sought for in disturbances of the digestive, circulatory, or of the generative apparatus. The treatment in vogue at Lassar's clinic is the following:

R. Beta naphthol. 10.0.
Sulph. præcipitat. 50.0.
Saponis virid.
Vaseline aa 20.0.

This salve is applied thickly to the affected portion of the skin either by a brush or a spatula, and left *in situ* for from half an hour to an hour. On the following day one notices some desquamation of the epidermis and slight irritation and retraction of the skin. This procedure is repeated every day until desquamation of the entire epider-

mis has taken place. Should much irritation be produced, the treatment may be temporarily stopped and the affected surface covered with an indifferent powder or with Lassar's paste. For especially stubborn cases the following modification of the ointment may be applied:

R. Pulv. cretæ albæ 5.0.
Beta naphthol.
Camphor
Vaseline aa 10.0.
Saponis virid. 15.0.
Sulphur præcipitat. 50.0.

The addition of the camphor increases the irritative power of the ointment, which in this form should only be left on the skin fifteen minutes.

Another formula which has been found serviceable in the treatment of acne is the following:

R. Resorcin
Zinc oxid
Amyli aa 5.0.
Vaseline 10.0.

—*Jour. of Cut. and Gen.-Urin. Dis.*, May, 1889.

ON THE INOCULATION OF CARCINOMA UPON ANIMALS.—Although carcinoma is a tumor producing metastases, it has so far been found impossible to inoculate it from men upon animals, or from animals upon animals. Transplantation has been attempted from dogs to dogs, or even to rabbits and guinea-pigs, but these attempts have proven futile. MR. HANAN, of Zurich, succeeded in transferring the carcinoma of a rat affected with papillar cancroide to two animals of the same species. He inoculated these two rats in the tunica vaginalis of the scrotum, which in these animals communicates with the peritoneum. At the end of seven weeks one of the rats died from carcinoma. The entire epiploon was covered with nodosities, some the size of a pea, some smaller. The axillary and inguinal glands were similarly affected. These tumors when examined under the microscope showed the same type of carcinoma as that from which the virus was taken. The autopsy of the second rat was made in the presence of Professor Koch, and disclosed analogous alterations.—*La Semaine Médicale*, No. 18, 1889.

TREATMENT OF ONYURIS VERMICULARIS.—GUBB, *London Med. Record and Allgem. Med. Centralz*, 1889, No. 16, recommends rectal injections of pure cod liver oil or an emulsion of it with eggs, as reliable and not irritating. Grimaud calls attention to the fact that Lallemand (Montpellier) obtained the most reliable results with natural sulphur waters. He (Grimaud) also had opportunity to convince himself that sulphur water is poisonous for intestinal worms. It may be used internally or per clyisma, and the worms will soon disappear without returning.—*Therapeutische Monatshcft*, 1889, No. 4.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, JUNE 1, 1889.

SPECIAL NOTICE.

At the moment of going to press a circular has been received calling attention to the "*American Medical Association Annual*," and seeming to represent the Medical Association, soliciting advertisements.

It is proper to state that THE JOURNAL is the only official organ of the Association, and is alone authorized to receive advertisements in its interest.

The Board of Trustees has full control of THE JOURNAL, and as neither the Board, nor its special Committee on Management, nor its editor has any knowledge on this subject, we are at a loss to know upon what authority such solicitations are made.

It is certainly not the purpose of the Association to be related to advertisers in any other manner, than through its official organ—THE JOURNAL.

DEVENTER'S METHOD OF DELIVERY OF THE
AFTER-COMING HEAD.

The utterances of DR. JOHN BARTLETT upon obstetrical topics always deserve and commonly receive close attention. It is the purpose of this note to discuss briefly his last contribution to the art of midwifery, "*A Study of Deventer's Method of Delivering of the After-Coming Head*."¹

As interpreted by Dr. Bartlett, Deventer's plan differs in essential points from the procedure in vogue, known as the Smellie-Veit method. The posture of the woman is identical with that commonly assumed at the present day—dorsal decubitus, hips elevated. As soon as the child has passed so far as the base of the thorax, extractive efforts are to be made, in a direction downward and a little backward. When the arms are within reach an examination of their relation to the head should be made. Should their position be favorable, that is, on either side of the head, resting anteriorly to the parietal protuberances, delivery may be at once proceeded with. But if the position be unfavorable it should be corrected, either by adjusting the arm to its proper site, or, in the event of that being impracticable, as in case the extremity were in front of the forehead, or behind the occiput, by bringing it down in accordance with established rules. From the moment that the head enters the pelvis the woman must be earnestly called upon to second the efforts of the accoucheur by bearing down with all her power. After the arrest of the chin at the pelvic floor, pressure should be made over the occipital end of the head as nearly behind the anterior wall of the pelvis as practicable, with the view of causing descent of the occiput, and a relieving extension of the head. In a typical case, the occiput appears under the pelvic arch, and the delivery is accomplished with the chin in forced extension, instead of flexion, while the arms are extended along the sides of the head.

The "particular advantages" of Deventer's plan over the Smellie-Veit method, according to Dr. Bartlett, are:

1. What Barnes might call the decomposition of the wedge of the shoulders; in lieu of the bis-acromial diameter presenting at the superior strait, it is the bis-axillary diameter.

2. The arms extended upon the head bridge over the space between it and the body; thus extended they (*a*) act as fenders for the cord, keeping open channels through which the funis may pass uncompressed; (*b*) they antagonize that spastic contraction of the uterus which, closing in upon the lower circumference of the after-coming head, is one of the causes of fatal delay in delivery in these cases.

¹"A Study of Deventer's Method of Delivering of the After-Coming Head." Transactions of the International Medical Congress. Ninth Session. Vol. ii. p. 438.

3. By this method the delivery of the after-coming head is very greatly simplified. In the majority of instances it may be unnecessary to interfere with the attitude of the head; Deventer claims that, with few exceptions, the head will "shoot through" both straits easily.

4. The delivery by extension is very much more expeditious than the ordinary method. Precious time is not lost in bringing down the arms, inserting the fingers in the child's mouth, etc. As a consequence, if the experience of Deventer is to be relied upon, it would seem to be safer for the mother, and very much safer for the child, than other methods.

Adequate evidence from clinical observation to support these propositions is not supplied by Dr. Bartlett in this essay. They are conclusions drawn purely from *à priori* considerations and from Deventer's alleged successful treatment of artificial breech presentations.

Dr. J. H. Chew,² of Chicago, has written an excellent history of one case of delivery by Deventer's method. As at present informed, this single case constitutes the only example of the procedure in practice that has been recorded within recent years. Charles T. Parkes, of Chicago, George Wheeler Jones, of Danville, Ill., Frank L. Wadsworth, of Chicago, and others, have indeed cited cases in which the method was successfully employed, but, in the absence of exact accounts of the conditions and indications present in such cases, the testimony of these gentlemen cannot be accepted as competent.

In this connection, it may be remarked that Dr. Bartlett's citation of Zweifel's statistics of version is not pertinent. Dr. Bartlett writes: "According to statistics presented by Zweifel, in 3,475 versions the mortality was 58.9 per cent. Says Deventer: 'If this operation of version and extraction of infants be cautiously and skillfully managed, the infant is not exposed to the danger of death.'" Upon the one hand, Zweifel's statistics, as a reading of the context shows, are drawn from cases in which internal version was performed under all possible indications. In many cases, the infants were dead before the operation was performed. They relate to the prognosis of version, not to the prognosis of extrac-

tion. Upon the other hand, no practitioner will accept Deventer's dictum that if his operation of version and extraction be cautiously and skillfully managed, the infant is not exposed to the danger of death. Experience teaches that in version and extraction, no matter how favorable the conditions may be, there is always grave danger of death of the infant.

This misuse of statistics may be allowed to pass as a rhetorical subterfuge—as an example of antithesis—but its bearing on the question under discussion must be absolutely rejected.

The fourth and third propositions, formulated by Dr. Bartlett, cannot be sustained. Note that the propositions are universal, that they include all cases. Now it is an obstetrical axiom, from which no man can withhold assent, that that procedure in these cases is safest for both mother and child that imitate most closely the natural mechanism of labor. The natural mechanism constitutes the most advantageous mode of delivery both with reference to the mother and the child. Neither will any one venture to deny that the natural mechanism of labor is most closely simulated by the Smellie-Veit method. The conclusion is obvious.

The Smellie-Veit method of manual aid, originally proposed by Mauriceau, in 1668, and modified by Lachapelle in 1821, consists first in the liberation of the arms, and secondly in the delivery of the head by flexion of the chin upon the sternum by the finger passed through the mouth to the lower jaw, and by traction applied chiefly to the shoulder through the fingers that fork-like are placed on either side of the neck.

In normal cases of natural or artificial breech presentation—these are included in Dr. Bartlett's proposition—the practice of Deventer's method means as forcibly remarked by Dr. Knox,⁴ the production of a malposition and then a hunt for a new method to escape from the difficulty. The second proposition seems too fanciful to analyze critically, while the first is manifestly untrue.

Deventer's method doubtless has its place, and under certain conditions may even come to be the operation of election. Thus Smellie points out cases of dystocia in which the procedure may be useful. He writes: "When the forehead is hindered from coming down into the lower part of the sacrum by an uncommon shape of the head

⁴ Transactions of Chicago Medical Society. loc. cit.

or pelvis, and we cannot extract it by bringing it out with a half-round turn at the os pubis; we must try Deventer's turn in the contrary direction."

ILLINOIS STATE MEDICAL SOCIETY.

The thirty-ninth Annual Meeting of this Society was held in Jacksonville, Ill., May 21, 22 and 23, 1889, and was attended by about 200 members. The season was pleasant, the city beautiful, the accommodations provided by the Committee of Arrangements convenient, and the members engaged harmoniously in the legitimate work of the Society. Reports and papers of interest pertaining to almost every department of the science and art of medicine were read and discussed with profit and with much less waste of time than usual. The meeting was called to order at 10 A.M. Tuesday by the President, Dr. C. W. Earle, of Chicago. In the absence of the Mayor, a brief and appropriate address of welcome was delivered by City Attorney Yates, and was responded to in behalf of the Society by Dr. N. S. Davis, of Chicago. In the evening the members of the Society and a large audience of citizens assembled in the Presbyterian Church to hear the President's Annual Address, and also a most interesting musical and literary entertainment by the pupils of the Illinois Institution for the Education of the Blind. Dr. C. W. Earle, the President, has been the attending physician of the Washingtonian Home of Chicago for many years, and thereby brought in close contact with many thousand inebriates; and his address, which was on the subject of "Inebriety and the Responsibility of Physicians in prescribing Alcoholic Remedies in the Treatment of Disease," was listened to with marked attention. He combated vigorously the doctrine that drunkenness was the result of a primary disease of the brain and nervous system, called *inebriety*, or in any considerable degree derived from hereditary influence. He claimed that three-fourths of those addicted to the use of alcoholic drinks were fully able to reform whenever they choose to make a judicious and earnest effort to do so. He admitted, however, that in one-fourth or perhaps less, the long continued use of alcohol had produced such structural changes as to render them incapable of self-control, and for such the State should provide suitable asylums and legal restraint on

the same principles that guide in the control of the insane.

The attention of the Society had been chiefly occupied during the day with the important subjects of Pneumonia and Diphtheria, they being presented both in the report of Dr. C. F. Robinson, of Wyandot, Chairman of the Committee on Practical Medicine, and a paper by Dr. J. A. Baxter, of Astoria, and by Dr. Geo. N. Kreider, of Springfield, in a paper on "Tepid Baths in the Treatment of Pneumonia." These papers and the discussions elicited by them, developed the important fact that in many parts of the State pneumonia had been more prevalent than usual during the months of February, March and April of the present year.

The Society was fully occupied with reports and papers on diseases of children, gynecology and obstetrics during the second day, and was entertained by a complimentary concert given by members of the Faculty of the Illinois Conservatory of Music of Jacksonville, in the evening. On the third day work was commenced at 8:30 A.M. and continued until near 2 P.M., after which the members were taken to the Hospital for the Insane. During the session, the time was occupied closely and profitably in considering the report of the Committee on Surgery, and volunteer papers by Drs. E. Andrews and A. E. Hoadley, of Chicago, and Dr. David Prince, of Jacksonville, and the report of the Committee on Ophthalmology and Otology by Dr. H. M. Starkey, of Chicago, and Dr. A. E. Prince, of Jacksonville.

Throughout the three days' sessions it was generally conceded that the Illinois State Medical Society had enjoyed no more pleasant or profitable meeting during its past history, than the one we have thus briefly outlined.

WAS IT A DECOY OR SILLY "CATCH," OR A REAL ATTEMPT TO GAIN POSSESSION OF A DIPLOMA, IN DUE FORM, UNDER THE PRETENSE OF HAVING IT CONFERRED UPON A "FRIEND?"

The following letter, dated Boston, Mass., April 12, 1889, was addressed to the Dean of the Medical Department of a University located east of the Alleghany Mountains, and by him forwarded to us:

"Dear Sir:—I take the liberty of writing you a confidential letter suggesting we exchange college honors. I

have the honor to be Dean of the Medical Department of a University in New England. If you will confer the degree of M.D., upon a friend of mine who is now a graduate in medicine, I will ask the Board of Trustees of the above-mentioned University to confer upon you, or one of your colleagues, the honorary degree of A.M. or LL.D., just as the person is qualified to receive. Hoping you will give this matter your immediate attention and forward an early reply, I am very truly,

"DR. P. RIPLEY.

"An envelope was enclosed for the reply directed to 'Dr. P. Ripley, 71 Cornhill, Boston, Mass.'"

Having a reliable correspondent in Boston, he was requested to inform us who Dr. P. Ripley was, and of what "Medical Department of a University in New England" he was Dean? In due time he replied saying that he did not find Dr. P. Ripley's name in either the last city directory or the last New England Medical Register; and further that "71 Cornhill" was the waiting-room of the Horse Railway Company, with no one there who knew of any such person as "Dr. P. Ripley." Whether the letter was intended for a *hoax* or a fraudulent attempt to obtain a diploma, it was equally disgraceful to its author.

EDITORIAL NOTES.

DR. CHAS. T. REBER died at his home, near Fancher, Ill., on the night of May 10, 1889, aged 53 years, 3 months and 22 days. He was a member of the American Medical Association. Was a surgeon of the 48th regiment Pennsylvania volunteers during the late war. He was a close student and a conscientious practitioner.

THE PROPOSED MEMORIAL TO THE LATE PROF. MOSES GUNN.—The Alumni and Faculty of Rush Medical College, Chicago, have been for some time engaged in the effort to raise by subscription a fund for the purpose of erecting in the college building a bronze to serve as a memorial of the late Professor Moses Gunn. Those purposing to contribute to the fund are reminded that their subscriptions cannot be received after the 15th of June. Sums varying from one to ten dollars can be sent to the College Clerk, Mr. F. J. Gould.

THE NEXT ANNUAL MEETING OF THE ILLINOIS STATE MEDICAL SOCIETY will be held in Chicago on the third Tuesday in May, 1890. The following are the officers for the ensuing year: President, Dr. John Wright, of Clinton; First Vice-President, Dr. J. P. Matthews, of Carlinville;

Second Vice-President, Dr. T. M. Cullimore, of Jacksonville; Permanent Secretary, Dr. D. W. Graham, of Chicago; Assistant Secretary, Dr. L. Ware, of Chicago; Treasurer, Dr. Thomas McIlvaine, of Peoria.

DR. H. ISAAC JONES, who has been an active practitioner in Scranton, Pa., for fifteen years past, has changed his residence to 118 Grant Ave., San Francisco, Cal.

SURGERY AT THE INTERCOLONIAL CONGRESS.

—The special correspondent of the *British Medical Journal*, in reporting the proceedings of the Surgical Section of the Intercolonial Medical Congress of Australasia, recently held at Melbourne, says: Mr. T. N. Fitzgerald, the President of the Congress, delivered the opening address and dealt with the perennial subject of club-foot, especially talipes equino-varus. He has added yet another to the many methods of treatment before us. After subcutaneous division of all tendons and resisting fascial bands, Mr. Fitzgerald introduces a chisel through a valved opening in the skin, and cuts through the neck of the astragalus and the greater process of the os calcis; he then wrenches the foot into position, overcoming any further resistance by "guarded powerful blows" of a mallet. All this is done upon a bloodless limb, and the part is firmly bandaged before Esmarch's cord is removed. Mr. Fitzgerald is able to report that "within a month the patient learns to walk upon his practically new feet." If other surgeons can achieve equally good results, this contribution to surgery is indeed a valuable one. It has distinct advantages over tarsectomy and the excision of bones; but, like these operations, it fails to deal with the faulty position of the os calcis beneath the astragalus. The treatment of hydatids naturally came up, and was exhaustively dealt with by Dr. Davies Thomas, of Adelaide. Dr. Thomas regards the tapping of cysts as both dangerous and ineffectual, and his tables show a mortality of 18.88 from the operation. Evidently more investigation upon this point is needed, for Victorian surgeons—as we are informed—find tapping and aspiration to be in most cases quite sufficient. Twenty successful cases of subrapubic lithotomy, by Mr. O'Hara, form no mean contribution to the subject; and Dr. Tremearne introduced an ingenious method of draining the bladder, which is capable of many applications.

THE CASINO.

Where the Sessions of the Association will be held.

American Medical Association

LIST OF OFFICERS AND PROGRAMME OF THE FORTIETH ANNUAL MEETING.

TO BE HELD AT NEWPORT, R. I., JUNE 25, 26, 27 AND 28, 1889.

GENERAL OFFICERS:

President—W. W. DAWSON, M.D., Cincinnati, Ohio.

Vice-Presidents—W. L. SCHENK, M.D., of Kansas; FRANK WOODBURY, M.D., of Pennsylvania;

H. O. WALKER, M.D., of Michigan; J. W. BAILEY, M.D., of Georgia.

Treasurer—RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Pa.

Permanent Secretary—WM. B. ATKINSON, M.D., 1400 Pine Street, Philadelphia, Pa.

Local Secretary—VALENTINE MATT FRANCIS, M.D., New York.

Librarian—C. H. A. KLEINSCHMIDT, M.D., Washington, D. C.

Chairman Committee of Arrangements—H. R. STORER, M.D., Newport.

The General Sessions will be held at the Music Hall, Bellevue Avenue, adjoining the Ocean House, and those of the Sections at the Newport Casino, also immediately contiguous, which for the first time in its history, and as an act of courtesy, is permitted by its Governors to be occupied for other than the purpose for which it was built.

PROGRAMME OF GENERAL SESSIONS.

FIRST DAY, TUESDAY, JUNE 25.

Assemble in Music Hall, Bellevue Avenue, at 11 A.M.

Meeting called to order by Dr. Horatio R. Storer, Chairman Committee of Arrangements.

Prayer. Rev. Thatcher Thayer, D.D. (Cong.), the senior clergyman of Newport.

Reading names of delegates and others thus far registered, by permanent Secretary, Dr. Wm. Atkinson, of Philadelphia.

Announcement of the programme for the day, of halls for the Sections, that papers not already listed be handed to Chairman of Committee of Arrangements for reference to appropriate Sections, that Judicial Council meet at 2 P.M. at Newport Casino, and that, to prevent the usual haste and confusion, the delegates from the different States hold their separate meetings, to elect members of the Nominating Committee, at 9:30 A.M. Wednesday, at the Music Hall, half an hour before the general session.

Address of Welcome by Hon. Thomas Coggeshall, Mayor of Newport; by Dr. Henry E. Turner, of Newport, President of State Board of Health, on behalf of the profession of Newport; and Hon. James H. Eldredge, M.D., of East Greenwich, ex-President of Rhode Island Medical Society, on behalf of the profession of Rhode Island.

Presidential Address, Dr. W. W. Dawson, of Cincinnati, Professor of Surgery in the Medical College of Ohio.

SECOND DAY, WEDNESDAY, JUNE 26.

Meeting called to order by the President of the Association at 10 A.M.

Prayer.

Reading continuation of registry list, of programmes for the day, and call for reports of elections to Nominating Committee.

Address on Medicine, by Dr. Wm. Pepper, of

Philadelphia, Provost of the University of Pennsylvania.

Report of the Trustees of THE JOURNAL.

Consideration of proposed Amendments to the Constitution.

Announcement of Nominating Committee, and that it will report at close of Thursday's general session.

THIRD DAY, THURSDAY, JUNE 27.

Meeting called to order by the President at 10 A.M.

Prayer.

Reading of continuation of registry list, and of programmes for the day, and notice that all new business must be introduced at to-day's session.

Address on Surgery, by Dr. Phineas S. Conner, of Cincinnati.

Introduction of New Business.

Report of Treasurer.

Report of Librarian.

Report of Rush Monument Committee.

Report of Nominating Committee.

FOURTH DAY, FRIDAY, JUNE 28.

Meeting called to order by the President at 9 A.M.

Prayer.

Reading of continuation of Registry list, and of programmes for the day.

Address on State Medicine, by Dr. W. H. Welch, of Baltimore.

Report of Necrologist.

Reading names of newly elected officers of the Sections and Delegates to Foreign Societies.

Introduction of the President-elect by the retiring President.

Response by the former.

Final Adjournment.

PROGRAMME OF SECTIONS.

Section on the Practice of Medicine, Materia Medica, and Physiology.

Chairman—F. C. Shattuck, M.D., Boston.

Secretary—G. A. Fackler, M.D., Cincinnati.

FIRST DAY—JUNE 25.

1. Address of the Chairman.

2. "On the Passage of Portal Blood into the General Circulation, and its Probable Relation to Toxæmia," by Charles G. Stockton, Buffalo, N. Y.

Discussion by William Osler, Baltimore; W. S. Tremaine, U. S. A.; John H. Musser, Philadelphia.

3. "Dioscorea Villosa—Wild Yam," by J. V. Shoemaker, Philadelphia.

4. "New Plan for the Treatment of Pneumonia," by G. R. Martine, Glen's Falls, N. Y.

5. "Some Clinical Aspects of Vomiting," by John H. Musser, Philadelphia.

6. "Differential Diagnosis of Varicella and Varioloid," by James T. Whittaker, Cincinnati.

7. "Some of the Rarer and Graver Forms of Cinchonism," by I. E. Atkinson, Baltimore.

SECOND DAY—JUNE 26.

1. "Chronic Endocarditis," by Francis DeLafield, New York City.

Discussion by William Pepper, Philadelphia; W. W. Gannett, Boston.

2. "On the Nature and Treatment of Chlorosis," by William Osler, Baltimore.

3. "Hydronephrosis, especially as Caused by Functional Disorders of Micturition," by Robert T. Edes, Washington, D. C.

4. "The Induction of Premature Labor in Bright's Disease," by James Tyson, Philadelphia.

5. "The Treatment of Epilepsy," by Charles F. Folsom, Boston.

6. "Alkaloidal Medication per Rectum, A New Method of Medication," by Elmer Lee, St. Louis.

7. "Reynaud's Disease," George M. Garland, Boston.

THIRD DAY—JUNE 27.

1. "The Etiology and Pathology of Typhoid Fever," by Victor C. Vaughan, Ann Arbor, Mich.

Discussion by Henry P. Walcott, Cambridge; William Osler, Baltimore.

2. "The Physiological Action of the Typhoid Fever Poison," by N. S. Davis, Jr., Chicago.

3. "Toxic Agents in the Blood as a Cause of Diseases of the Nervous System," by M. R. Crain, Rutland, Vt.

4. "Some Thoughts on the Etiology, Pathology, and Therapeutics of Phthisis Pulmonalis," by W. L. Schenck, Kansas City.

5. "Food in the Treatment of Consumption," by Solomon Solis-Cohen, Philadelphia.

6. "Trophopathy in Fatty and Fibroid Degenerations, with Presentation of Cases of Cure."

7. "Heat as a factor in Disease," by John H. Hollister, Chicago.

FOURTH DAY—JUNE 28.

1. "The Prophylaxis of Tuberculosis," by James C. Wilson, Philadelphia.

2. "Signs in Disease," by H. M. Brown, Hillsboro', Ohio.

3. "Ulcerative Endocarditis," by J. G. Truax, New York City.

4. "Myalgia," by Gustavus Eliot, New Haven, Conn.

5. "Veratrum Viride in the Treatment of Disease," by Thomas Legaré, Charleston, S. C.

6. "Stomach Rest and Cleanliness," by Mary E. Baldwin, Newport.

Secretary—A. B. Carpenter, M.D., Cleveland.

1. "Note on the Use of Boric Acid in Gynæcic Practice," by W. W. Potter, M.D., Buffalo.

2. "Bimanual Palpation as a Means of Diagnosis in Diseases of the Female Pelvic Organs," by Paul F. Mundè, New York City.

3. "Series of Five Hundred Confinements in a Maternity," by Joseph Price, Philadelphia, Pa.

4. "Observations on Abdominal Section, based on Two Hundred and Fifty Cases," by James B. Hunter, New York City.

5. "A New Procedure of Colpoperineoplasty by Glissement," by A. Doleris, Paris, France.

6. "Stricture of the Urethra in Women," by Ely Van de Warker, Syracuse, N. Y.

7. "The Inversion of the Uterus; Reduction by a New Method; Exhibition of Instruments," by Henry O. Marcy, Boston, Mass.

8. "Observations on Abdominal Surgery, with Report of One Hundred Consecutive Cases Done in the Past Year," by W. Gill Wylie, New York City.

9. "Concealed Pregnancy, Its Relation to Abdominal Surgery," by A. Vander Veer, Albany, N. Y.

10. "The Routine Management of Cases of Acute Intestinal Obstruction," by J. Greig Smith, Bristol, England.

11. "The Medals of Benjamin Rush, Obstetrician," by Horatio R. Storer, Newport, R. I.

12. "The Field and Limitations of Supravaginal Hysterectomy, and Methods of Operating," by L. S. McMurtry, Danville, Ky.

13. "Casuistry in Obstetrics," by Theophilus Parvin, Philadelphia, Pa.

14. "Fœtal Pathology," by W. H. Taylor, Cincinnati, Ohio.

15. "Tetanus following Ovariectomy," by Joseph Tabor Johnson, Washington, D. C.

16. Prof. J. Veit, Berlin, Germany. (Subject not given.)

17. "The Obstetrician as a Counselor," by Thomas Opie, Baltimore, Md.

18. "Injuries to the Bladder during Laparotomy," by A. Reeves Jackson, Chicago, Ill.

19. "Craniotomy and its Indications," by Joseph Hoffman, Philadelphia, Pa.

20. "Glandular Endometritis, Illustrated with Microscopic Projection," by Samuel N. Nelson, Boston, Mass.

21. "Electrical Treatment of Salpingitis, with Observations," A. Apostoli, Paris, France.

22. "Pelvic Abscess in the Female," by Wm. H. Parrish, Philadelphia, Pa.

23. "The Recognition and Treatment of Lacerations of the Cervix by the Obstetrician," by Henry C. Coe, New York City.

24. DeLaskie Miller, Chicago, Ill. (Subject not given.)

25. Prof. Gusserow, Berlin, Germany. (Subject not given.)

Section of Obstetrics and Diseases of Women.

Chairman—W. H. Wathen, M.D., Louisville.

26. "Reasons for Drainage in Ovariectomy," by Hampton E. Hill, Saco, Me.

27. "When and What Kind of Obstetrical Forceps Should be Used," by Wm. S. Stewart, Philadelphia, Pa.

28. "Chronic Cystitis in the Female," by Augustus P. Clarke, —, Mass.

29. "Results of Removal of Uterine Appendages After One or More Years," by S. C. Gordon, Portland, Me.

30. "The Indications for, and Limits of, the Operation for the Removal of the Uterine Appendages," by E. E. Montgomery, Philadelphia, Pa.

31. "Observations in Connection with S. Weir Mitchell's Mode of Producing Fat and Blood," by W. H. Bond, St. Louis, Mo.

32. "Peritoneal Effusions," by Wm. H. Meyers, Ft. Wayne, Ind.

33. "The Rectification of Malpositions of the Head by Rotation with the Forceps," by Edward J. Ill, Newark, N. J.

34. "Pregnancy in the Retroverted Uterus, with Cases," by James R. Chadwick, Boston, Mass.

35. "The Therapeutic Value of Electricity in Gynecology," by L. S. Fox, Lowell, Mass.

36. "Alexander's Operation, with a New Method of Securing the Round Ligaments," by A. B. Carpenter, Cleveland, Ohio.

37. "The Use of Glycoboron in Gynecology," by Wm. Thornton Parker, Providence, R. I.

38. Bache McE. Emmet, New York City. (Subject not given.)

39. "Emmet's Buttonhole Operation," by Virgil O. Hardow, Atlanta, Ga.

40. "On the Treatment of Cancer of the Uterus," by Thomas Moore Madden, Dublin, Ireland.

41. W. E. B. Davis, Birmingham, Ala. (Subject not given.)

42. "A New Two-Ways Catheter for Uterine Irrigation," by A. Cordes, Geneva, Switzerland.

43. "The Application of Forceps to Transverse and Oblique Positions of the Head; Description of a New Forceps," by Henry D. Fry, Washington, D. C.

44. "The Galvanic Current in Gynecology," by A. Laphorn Smith, Montreal, Canada.

45. "Tubal Pregnancy; Delivery at Six Months per Vias Naturales; Recovery," by Wm. M. Fineley, Altoona, Pa.

46. Thomas E. McArdle, Washington, D. C. (Subject not given.)

47. George R. Shepherd, Hartford, Conn. (Subject not given.)

48. W. B. Carson, St. Louis, Mo. (Subject not given.)

Section on Surgery and Anatomy.

Chairman—N. P. Dandridge, M.D., Cincinnati.

Secretary—W. O. Roberts, M.D., Louisville.

TUESDAY, JUNE 25—FIRST DAY.

1. "On the Surgery of the Lateral Ventricles of the Brain," by W. W. Keen, Philadelphia.

Discussion, J. Collins Warren, Boston.

2. "Concussion of the Spine in its Medico-Legal Aspect," by H. H. Smith, Philadelphia.

Discussion by Herbert Judd, Galesburg; B. A. Watson, Jersey City; Edmund Andrews, Chicago.

3. "Surgery of Peripheral Nerves," by Maurice Richardson, Boston.

4. "Pathology and Treatment of Chronic Sciatica," by J. G. Carpenter, Stanford, Ky.

5. "Suspension and Extension in the Treatment of Chronic Sciatica," by C. C. Hunt, Dixon, Ill.

6. "Arthroctomy of Knee Joint," by E. H. Bradford, Boston.

WEDNESDAY—SECOND DAY.

1. "The Treatment of Stone in the Urinary Bladder," by W. T. Briggs, Nashville.

2. "Litholapaxy," by A. T. Cabot, Boston.

3. "Litholapaxy in Children," by Dudley Allen, Cleveland.

Discussion—"Choice of Operation for Stone," J. W. S. Gowley, New York; C. T. Gardner, Providence.

4. "Management and Treatment of Large Hernia," by J. Collins Warren, Boston.

5. "Open Wound Treatment of Hernia," by H. O. Marcy, Boston.

6. "Properitoneal Hernia," by Thomas W. Dulles, Philadelphia.

7. "Epicystic Surgical Fistula for Relief of Vesical Catarrh," by J. D. S. Davis, Birmingham, Ala.

THURSDAY—THIRD DAY.

1. "Some Further Considerations and Statistics of Abdominal Sections for Traumatism," by Thos. S. K. Morton, Philadelphia.

2. "Pelvic Surgery by Abdominal Section, its Past, Present and Future," by Jos. W. Price, Philadelphia.

3. "Peritonitis," by J. M. Baldy, Philadelphia.

4. "Drainage in Abdominal Surgery," by Charles B. Penrose, Philadelphia.

5. "A Plea for Early Abdominal Work," by M. Price, Philadelphia.

6. Title not received, by L. S. McMurtry.

7. "Chylous Cyst of Mesentery, with Report of a Case," by N. B. Carson, St. Louis.

8. "The Use, 25 Years Ago, of Polarity, Locating the whereabouts of a Lead Bullet in the Body of a Brave Soldier," by Addinell Hewson, Philadelphia.

9. "Fistula in Ano," by J. M. Matthews, Louisville.

10. "Wiring the Patella in Old Ununited Fracture," by W. C. Will, Danbury.

11. "The Healing of Aseptic Bone Cavities by Implantation of Antiseptic Decalcified Bone," by N. Senn, Milwaukee.

12. "Electrolysis in the Treatment of Stricture of the Rectum," by Robert Newman, New York.

13. "A New Rib Cutter, and a Case of Resection of Ribs for Drainage of a Pulmonary Cavity," by Charles Denison, Denver.

14. "The Absorption of Dead Bone," J. B. Hopkins, Philadelphia.

Section on State Medicine.

Chairman—J. Berrien Lindsley, M.D., Nashville, Tenn.

Secretary—S. T. Armstrong, M.D., U. S. Marine Hospital Service, New York, N. Y.

TUESDAY—JUNE 25, 2 P.M.

Section called to order. Announcement of titles of volunteer papers to be read Friday, June 28.

"The American Medical Association and its Relations to the Public Health," by N. S. Davis, Chicago, Ill.

"International Comity in State Medicine," by John B. Hamilton, Washington, D. C.

"Volunteer Sanitary Organizations as an Aid to Public Boards of Health," by H. R. Storer, Newport, R. I.

"The Importance and Essential Needs of Local Boards of Health," by W. C. Rives, New York, N. Y.

"Modern Sanitary Conditions," by Geo. E. Waring, Jr., Esq., Newport, R. I.

"Rural Sanitation," by Thos. M. Flandrau, Rome, N. Y.

"Report of the Committee on Uniform Medical Legislation in the United States," by Perry H. Millard, Chairman.

"Medical Legislation in the United States," by Perry H. Millard, St. Paul, Minn.

WEDNESDAY—JUNE 26.

Called to order: reading of minutes of preceding meeting.

Annual Address of the Chairman, by J. Berrien Lindsley, Nashville, Tenn.

1. "Quarantine of the Future," by W. C. Van Bibber, Baltimore, Md.

Discussion opened by J. H. VanDeeman, Nashville, Tenn.

2. "Etiological Relations of Water to Disease," by F. L. Sim, Memphis, Tenn.

3. "The Purification of Drinking Water for Cities," by Charles V. Chopin, Providence, R. I.

4. "Bacteriological Examination of Several Native Mineral Waters in the Bottled State," by George Minges, Dubuque, Ia.

5. "Report of the Standing Committee on

Meteorological Conditions," by N. S. Davis, Chairman.

6. "The Climatic Causation of Consumption," by Henry B. Baker, Lansing, Mich.

7. "Climatological Characteristics of Salt Lake City," by F. S. Bascom, Utah.

8. "Ranch Life in Texas for Consumptives," by J. R. Briggs, Dallas, Tex.

9. "Biometry, or the Measure of Life as Applied to Life Assurance," by Charles Everett Warren, Boston, Mass.

THURSDAY—JUNE 27.

Called to order: reading of minutes of preceding meeting.

Election of officers for the Section for the ensuing year.

1. "The Necessity for Sanitary Supervision of Schools," by George H. Rohé, Baltimore, Md.

Discussion opened by W. L. Schenek, Osage City, Kas.

2. "Do the Sanitary Interests of the United States Demand the Annexation of Cuba?" by Benjamin Lee, Philadelphia, Pa.

3. "Personal Disinfection in Scarletina," by L. D. Waterman, Indianapolis, Ind.

4. "Report of the Committee on Fœticide," by I. M. Quimby, Chairman.

5. "The Causation and Restriction of Infantile Mortality," by V. C. Vaughan, Ann Arbor, Mich.

6. "Is it Detrimental to the Health of Passengers on Shipboard to Convey to Port the Bodies of Persons who Die at Sea of Non-contagious Disease?" by I. N. Quimby, Jersey City, N. J.

7. "Disposal of House Refuse," by Alfred L. Carroll, New York, N. Y.

8. "The Benefits of Sanitation Applied to Obstetrical and Gynecological Surgery," by T. A. Ashby, Baltimore, Md.

9. "Stamina," by A. N. Bell, Brooklyn, N. Y.

FRIDAY—JUNE 28.

Called to order: reading of minutes of preceding meeting.

Reading of volunteer papers.

Section on Ophthalmology.

Chairman—George E. Frothingham, Ann Arbor, Mich.

Secretary—G. C. Savage, Nashville, Tenn.

FIRST DAY—JUNE 25.

1. Address by the Chairman, Geo. E. Frothingham, Ann Arbor, Mich., "The Need of Discussing Ophthalmic Subjects."

2. "The Prevention of Pain and the Improvement of the Stump following Evisceration of the Eye," by A. E. Prince, Jacksonville, Ill.

3. "What can we do to Induce the Government to Make the Census of 1890 Contribute Efficiently to a Clear Conception of the Causes of

Blindness in the United States," by Robert Tilley, Chicago.

4. "Advances in Our Knowledge of some Cerebral Ocular and Intra-Ocular Lesions which Facilitate the Diagnosis and Treatment of Important Diseases," by H. W. Williams, Boston.

5. "Ocular Symptoms of Diseases and Injuries of the Spinal Cord," by J. F. Fulton, St. Paul, Minn.

6. "Impaired Vision as a Result of Sunstroke," by A. R. Baker, Cleveland, O.

7. "Some Cases of Inflammation and Atrophy of the Optic Nerve, with Special Reference to Etiology and Prognosis," by J. L. Thompson, Indianapolis, Ind.

8. "The Non-Surgical Treatment of Strabismus Convergens," by E. J. Gardiner, Chicago.

9. "Tobacco Amaurosis," by Leartus Connor, Detroit.

10. "Paralysis of Accommodation from Concussion of Eyeball; Treatment," by Eugene Smith, Detroit, Mich.

SECOND DAY—JUNE 26.

1. "A Case of Sympathetic Irido-Choroiditis, Induced by Sarcoma of the Choroid, and Appearing Five Days After the Enucleation of the Sarcomatous Eye," Interesting Clinical History and Final Recovery," by F. C. Hotz, Chicago.

2. "Tumors of the Optic Nerve," by S. C. Ayres, Cincinnati.

3. "The Needless and Annoying Restraints after Eye Operations," by J. J. Chisolm, Baltimore.

4. "The Advantage of a Preliminary Iridectomy in Cataract Extraction," by LeRoy Dibble, Kansas City.

5. "Keratitis Trachomatosis," by J. H. Thompson, Kansas City.

6. "Gradation of Lenses," by Dudley S. Reynolds, Louisville.

7. "Glaucoma Fulminans, after Operations," by P. D. Keyser, Philadelphia.

THIRD DAY—JUNE 27.

1. "Traumatism of the Eye," by C. M. Hobby, Iowa City.

2. "Ametropia in Schools," by F. B. Tiffany, Kansas City.

3. "The Ametropiæ and Their Relation to Insufficiencies of the Recti Muscles," by J. W. Wright, Columbus, O.

4. "Embolus of the Inferior Branch of the Retinal Artery Visible with the Ophthalmoscope, Disappearance of Embolus and Recovery of the Greater Part of Visual Field under Massage and Nitrite of Amyl," by H. Gifford, Omaha, Neb.

5. "Intra-Ocular Diseases Caused by Chronic Rhinitis," by J. G. Sinclair, Nashville, Tenn.

Other papers have been promised, but as yet the subjects have not been announced. All who expect to read papers are requested to send the

title at once, either to the Chairman or Secretary of the Section, otherwise they can not be placed upon the programme of proceedings, which will be published soon by the Committee of Arrangements.

Section on Diseases of Children.

Chairman—J. A. Larrabee, M.D., Louisville.

Secretary—C. J. Jennings, M.D., Detroit.

FIRST DAY, JUNE 25.

1. "The Management of Infants during the First Year," by T. B. Greenley, West Point, Ky.

2. "Cow's Milk for Infant Food," by E. F. Brush, Mt. Vernon, N. Y.

3. "Summer Diarrhoea and Dysentery" by N. Gulmann, St. Louis, Mo.

4. "Intestinal Diseases of Children during Hot Weather," by Peter Hooper, Philadelphia, Pa.

5. "Cholera Infantum, its Etiology and Treatment," by Steele Bailey, Stanford, Ky.

SECOND DAY, JUNE 26.

1. "Heart Failure in Diphtheria," by Geo. Wheeler Jones, Danville, O.

2. "Intubation of the Larynx, with Reports of Cases," by F. E. Waxham, Chicago, Ill.

3. "Scarlatina" by C. R. Earley, Ridgeway, Pa.

4. "Pathology and Treatment of Certain Complications of Scarlet Fever," by Talbot Jones, St. Paul, Minn.

5. "The Value of Hydrogen Dioxide in the Treatment of Diseases of Children," by Marcus P. Hatfield, Chicago, Ill.

6. "A Rule with Penalty in Public Schools," by David I. Booth, Sparta, Ill.

7. "Poliomyelitis Anterior Acuta," by S. P. Deahofe, Potsdam, O.

THIRD DAY, JUNE 27.

1. "Serious Abdominal Injuries of Children," Resulting from Traumatism Seemingly Trivial," by I. N. Love, St. Louis, Mo.

2. "Visceral Neuralgias in Children," by J. C. Wilson, Philadelphia, Pa.

3. "Atropine in Eneuresis," by Wm. Perry Watson, Jersey City, N. J.

4. "Adherent Præputium Clitoridis as a Cause of Chorea, with Report of a Case," by C. Henri Leonard, Detroit, Mich.

5. "A Further Study of the Cardiac Relations of Chorea," by Wm. Osler, Philadelphia, Pa.

6. "The Treatment of Heart Disease in Children," by J. A. Robison, Chicago, Ill.

FOURTH DAY, JUNE 28.

1. "The Physical Education of Children," by A. H. P. Leuf, Philadelphia, Pa.

2. "The Treatment of Tubercular Bone Lesions before the Joint is Invaded," by V. P. Gibney, New York.

3. "Notes on Surgical Diseases of Children," by Edwin Brock, St. Louis, Mo.

4. "Spine Bifida," by Norman Teal, Kendallville, Ky.

5. "Trismus Nascentiam," by A. V. Williams, Frankfort, Ky.

Papers have been promised from Jerome Walker, Brooklyn, N. Y., W. B. Atkinson, Philadelphia, Pa.

Section of Dental and Oral Surgery.

Chairman—F. H. Rehwinkel, Chillicothe, O.

Secretary—E. S. Talbot, Chicago.

TUESDAY, JUNE 25.

Address by T. H. Rehwinkel, Chairman.

1. "Facial Neuralgia Associated with Pregnancy," by W. W. Allport.

WEDNESDAY, JUNE, 26.

1. "Diseases of the Antrum," by Wm. Carr.

2. "Fissures," by R. R. Andrews.

THURSDAY, JUNE, 27.

1. "Care of the Teeth of Pregnant Women," by John Marshall.

2. "Statistics of Irregularities of the Teeth of Normal Individuals, the Idiotic, Deaf and Dumb, Blind and Insane," by Eugene S. Talbot.

Numerous other papers have been promised.

Section of Medical Jurisprudence.

Chairman—J. G. Kiernan, M.D., Chicago.

Secretary—S. C. Evans, M.D., Baltimore.

FIRST DAY, JUNE 25.

1. "History of Medical Jurisprudence," by Judge Amos G. Hull, New York.

SECOND DAY, JUNE 26.

1. "Tests of Insanity," by H. N. Moyer, Chicago.

2. "Monomania," by Clark Bell, New York.

3. "Legal Decisions on Insanity"—Chairman's Address, by Jas. G. Kiernan, Chicago.

4. "Massachusetts Insanity Laws," by T. W. Fisher, Boston.

5. "Illinois Insanity Laws," by Harriet C. B. Alexander, Chicago.

THIRD DAY, JUNE 27.

1. "Legal Aspects of Inebriety," by T. L. Wright, Bellefontaine, Ohio.

2. "Inebriate Criminals," by T. D. Crothers, Hartford, Conn.

3. "Social Aspects of Alcoholism," by E. C. Spitzka, New York.

FOURTH DAY, JUNE 28.

1. "Spinal Concussion," by S. V. Clevenger, Chicago.

Section on Dermatology and Syphilography.

Chairman—L. Duncan Bulkley, New York.

Secretary—W. T. Corlett, Cincinnati, O.

FIRST DAY, JUNE 25.

1. Address by the Chairman, "Recent Advances in the Treatment of Diseases of the Skin."

2. Discussion on "The Treatment of Tinea Tonsurans," opened by W. T. Corlett, and Henry Fleischner."

3. "The Prophylaxis of Ringworm of the Scalp," by Fred. J. Levisneur, New York.

4. "Some notes on Hoang-nan," by J. V. Shoemaker, Philadelphia.

5. Analysis of 250 Cases of eczem-seborrhoicum," by George T. Elliot, New York.

6. "Prurigo hiemalis, or Winter Itch," by W. T. Corlett, Cleveland, Ohio.

7. "Dermatitis Exfoliativa," by E. N. Brush, Philadelphia.

SECOND DAY, JUNE 26.

1. "Discussion on "The Indications for and Duration of the Treatment of Syphilis, opened by L. Duncan Bulkley, or another.

2. "The Positive Diagnosis of Syphilis," by Ephraim Cutter, of New York.

3. "On Pruritus," by Henry Fleischner, New Haven, Conn.

4. "A Case of Painful Subcutaneous Neuroma (Neuro-fibroma)," by J. Abbott Cantrell, Philadelphia.

5. "Relations between Acne and Diseases of the Nasal Cavity," by Carl Seiler, Philadelphia.

6. "Answers to questions Deposited in Question Box Relating to Dermatology or Syphilography.

THIRD DAY, JUNE 27.

1. "A Case of Kraurosis Vulvæ," by A. H. Ohman-Dumesnil, of St. Louis, Mo.

2. "Use and Abuse of Soap and Water," by Merrill Ricketts, Cincinnati, O.

3. "The Treatment of Felon without Incision," by J. S. Miller, York, Penn.

4. "The Early Recognition and Treatment of Epithelioma," by L. Duncan, Bulkley, New York.

Section on Laryngology and Otology.

Chairman—W. H. Daly, M.D., Pittsburg.

Secretary—E. F. Ingals, M.D., Chicago.

1. "The Third Tonsil; Its Important Relation to Naso-Pharyngeal and Naso-Aural Catarrh," by Joseph A. White.

2. "Adenoid Hypertrophy of Vault of Pharynx—Pathology and Treatment," by Bryson Delevan.

3. "The Benefits to be Derived from the Radical Operation for the Relief of Nasal Stenosis," by Holbrook Curtis.

4. "Obstruction of the Nares Causing Nervousness," by Hal Foster.

5. "Empyema of the Frontal Sinus," by Geo. A. Richards.

6. "Clinical Notes," by J. D. Arnold.

7. Short Address, by Lennox Brown.

8. "An Analysis of One Hundred Cases of Cough Cured by Adoption of Operative Procedure in the Treatment of Existing Morbid State of Nasal Cavities," by J. E. Schadle.

9. "Clinical Observations in a Number of Cases," by Carl Seiler.

10. "A New Gag, and Some Conservative Observations about Intubation," by Chas. Denison.

11. "Internal Ear Deafness, Illustrated with Cases," by J. G. Carpenter.

12. "On the Value of Antiseptic Treatment of and Protection of Membrana Tympani in Perforation," by Laurence Turnbull.

13. "Report of Cases of Dangerous Middle-Ear and Mastoid Inflammations, which followed Treatment of Naso-Pharynx," by J. L. Thompson.

14. "Observations upon the Effect of Nasal Obstruction on the Middle-Ear," by F. Whitehall Hinkel.

15. "The Indications for the Excision of the Drumhead of the Ear," by Samuel Sexton.

16. "The Possible Danger to Middle-Ear as a Result of Nasal Atomization," by C. W. Richardson.

17. "Nasal Polypi in Children, and Double Uvula," by John McKenzie.

18. "The Relation of Tonsillitis to Rheumatism," by S. J. Radcliff.

19. "Morbid Perforations of Nasal Septum," by A. B. Thrasher.

20. "Perforating Ulcer of the Septum Narium," by Max Thorner.

21. "Chronic Obstipation of the Nares; Hernia," by W. Freudenthal.

22. "Affections of the Throat as Evidence of Diseases in other Localities," by Jas. E. Logan.

23. "Epilepsy Caused by Intra-Nasal Disease," by F. S. Crossfield.

24. "Effects of Natural Gas upon Upper Air Passages," by D. W. Rankin.

25. "The Influence of Disorders of Digestion on Catarrh of Air Passages," by A. M. Duncan.

26. "The Treatment of Acute Naso-Pharyngeal Catarrh," by S. S. Bishop.

27. "Congenital Occlusion of Naso-Pharynx, with Report of Two Cases," by F. O. Stockton.

28. "On the Use of Menthol in Upper Air Passages," by Frank H. Potter.

29. "Menthol in Laryngeal Phthisis," by C. H. Knight.

30. "Sclerosis of Mastoid Cells," by J. B. Lip-pincott.

31. "Malignant Tumors of Larynx," by H. A. Johnson.

32. "Laryngeal Gummata," by Robert Levy.

33. Glandular Hypertrophies at the Base of Tongue," by John O. Roe.

34. "A Case of Acute Rheumatic Laryngitis of Gonorrhœal Origin," by Wm. K. Simpson.

35. "Abscess of the Antrum of Highmore; Its Diagnosis and Treatment," by J. H. Bryan.

36. Nasal Bacteria," by Jonathan Wright.

37. "Treatment of Cystic Goitre," by E. Fletcher Ingals.

Papers are also expected from the following, but the titles have not been received:

Drs. E. L. Shurly, Louis Jurist, Wm. Porter, J. Mount Bleyer, Chas. E. Sajous, Thos. Legaré, Chas. Stover Allen, J. Solis-Cohen, C. E. Bean, F. I. Knight, W. E. Casselberry, E. R. Lewis.

Others desirous of reading papers in any of the Sections should at once send the title of their paper to Dr. H. R. Storer, Newport R. I., and to the Chairman of the Section in which they wish to read it.

HOTELS.

In Newport.—Ocean House, Bellevue Ave., \$4 per day, (special rate); The Aquidneck, Pelham St., \$3 per day, (special rate); Brayton House, Pelham St.; Cliff Ave. Hotel, on the Cliffs, \$2.50-\$3; Perry House, Washington Square; Central House, 14 Bath Road.

In Jamestown.—(Eighteen minutes by steam ferry from Newport. Boat making trips about every hour, each way.) Bay View House, C. T. Knowles, \$2 per day; Gardner House, Gardner & Littlefield, about \$2 per day; Prospect House, C. E. Weeden, \$2 per day; Champlins', Wm. A. Champlin, \$1.50 per day.

PRIVATE BOARDING HOUSES. \$1.25 TO \$5 PER DAY.

Ailman, Miss R. L., 62 Spring Street; Allen, Samuel, 79 Washington; Bailey, Mrs. John C., 84 John; Barker, Mrs. James P., 15 Clinton Ave.; Barker, Mrs. Jos. P., 304 Broadway; Bateman's, Brenton's Point; Bateman, Mrs. Joseph, Kay St. House; Bliss, Mrs. W. H., 6 West Marlboro; Bosworth, Mrs. P. S., 35 Spring; Bryer, Mrs. Peleg, 12 Park; Burbridge, Mrs. J., cor. Corné and Mill; Clark, Mrs. A. M., 42 John; Dame, Miss E. M., 78 Broadway; Dawley, Mrs. S. E., 24 John; Eldredge, Mrs. A. E., 36 Washington; Ellis, Mrs. J. J., 72 John St.; Essex, J. J., 252 Thames; Finch, Mrs. J. B., 27 High; Gifford, Miss M. A., 25 Farewell; Hall, Mrs. E. A., 137 Broadway; Henderson, Mrs. H. R., 1 Wanton Ave.; Kreis, Mrs. H. K., 101 Prospect Hill St.; Nason, Mrs. Geo., 28 John; Peckham, E. Truman, 7 Arnold Ave.; Peters, Mrs. Anton, 34 Broadway; Richardson, J. D., Jr., 13 Summer; Robinson, Mrs. M. J., 14 Catherine; Rudolph, Mrs., 106 Church; Russell, James M., 49 Washington; Seabury, Mrs. T. M., 16 Mann; Sisson,

Mrs. A. P. 81 Touro; Snow, Mrs. A. C., 8 Pelham; Swasey, Mrs. J. H., 74 Spring; Thurston, Mrs. Harriet, 92 Division; Townsend, H. A., 15 Rhode Island Ave.; Weaver, Mrs. Jacob, 216 Thomas St.; White, Mrs. Annie, 63 Broadway; Wilbour, Misses M. A. and H. L., 50 Washington; Wilbur, Mrs. A. A., 131 Church; Williamson, Mrs. E. F., 33 Ann.

PRIVATE LODGINGS (WITHOUT MEALS). FIFTY CENTS TO \$1 PER DAY.

Bishop, Mrs. A. H., 16 Chestnut St.; Brown, John, 18 Newport Ave.; Bullock, Mrs. Joseph H., 87 John; Congdon, Mrs. C. T., 100 Spring; Finlay, Mrs. A. M., 80 John; Goddard, Mrs. L., 38 John; Greene, A. M., 54 John; Hammond, Mrs. C. E., 12 Appleby Ave.; Kelley, Mrs. G. H., 16 Bay View Ave.; Lawton, H. R., 66 John; Leddy, Mrs. M. S., 38 Franklin; Lee, Mrs. Wm. H., Corné St.; Martin, Miss, L. D., corner John and Martin Sts.; Milne, Mrs. W. O., 8 Everett; Mumford, Miss H. E., 8 N. Baptist St.; Ordway, Mrs., 84 Division; Pitman, Mrs., corner Martin and Prospect Hill Sts.; Simmons, Mrs. W. B., 9 Meeting St.; Slocum, Mrs. Geo. S., 35 Green; Stanton, Mrs. R. H., 42 Washington Square; Stewart, Mrs. J. C., 80 Division; Titus, Mrs. I. W., 14 Everett; Weeden, Mrs. C. D., 2 Allen Ct.

Notice to Exhibitors.

For the accommodation of exhibitors the local committee of arrangements has contracted for the erection of a temporary building as the most feasible and advantageous provision which can be made for the display. This building is to be put up on a lot the use of which is gratuitously given for the purpose by John G. Weaver, Esq. The lot adjoins the lot on which stands the Music Hall, in which the general sessions of the Association are to be held, and it is also contiguous to the Ocean House, the largest hotel. The contract provides for a one story, sloping roof structure, twelve feet high at the eaves, built of planed, matched, grooved and tongued boards, the studing and floor planed, with windows eight feet apart from centre to centre, the whole wind and rain proof. This building is to be made of a size to accommodate such accepted exhibitors as have made application for space previous to May 30. By the return of the material to the builder after use the net cost of the building is to be at the rate of \$19.00 for each 100 square feet of floor space. Out of this floor space must be taken room for aisles, and there will be some few incidental small expenses, as for night watchman, safeguards against fire, etc., so that the cost to exhibitors will be at a rate somewhat exceeding \$20.00 for each 100 square feet of floor space occupied. The committee will try to keep the sum total of expense as low as possible for satisfactory accommo-

dations, and to divide the whole cost equitably among the exhibitors. The building is to be so situated in a large lot as to have air and light on all four sides; there is to be an entrance at each end, and there can be no poor location in it. In the assigning of space regard will be had as far as possible to priority of applications, to expressed preferences and varied needs of exhibitors, and to economy of space. The committee consider themselves as acting as agents of the exhibitors for the mutual convenience of the whole, and they can assume no responsibility for the safety of exhibits. If insurance of any kind on exhibits be desired, it should be procured by the owners.

C. A. BRADSETT,

E. P. ROBINSON,

Sub-Com. on Exhibits, Am. Med. Association.

Railroad Arrangements.

The Local Committee of Arrangements and the Committee of Transportation at Newport hope to be able to announce definitely in the next issue of THE JOURNAL, that arrangements have been perfected whereby members and those who accompany them to the forthcoming meeting will be able to purchase their tickets at a rate not to exceed one fare and a third for the round trip. It is expected that the various railroads will grant this courtesy, and whether the tickets will be sold on the certificate plan for the entire distance, or whether round trip tickets will be sold at the starting-point to the place of meeting, are subjects that are being actively discussed by the various Traffic Associations at the time we go to press for this issue of THE JOURNAL.

Dr. Liston H. Montgomery, 189 Randolph St., Chicago, has been appointed a member of the Transportation Committee.

SOCIETY PROCEEDINGS.

The American Surgical Association.

Annual Meeting, held in the New Army Medical Museum, Washington, May 14, 15, and 16, 1889.

(Continued from page 751.)

DR. CLAUDIUS H. MASTIN, of Mobile, read a paper on

HERNIA—A COMPARISON OF THE VARIOUS METHODS ADOPTED FOR ITS RADICAL CURE,

inviting discussion of their respective merits.

Reference was first made to the great frequency of this condition. The Census Reports of 1880 show that of the total number of deaths, 1 in

every 600 was due to hernia, and out of 1,236 deaths from hernia, 141 occurred in children under one year of age. A historical review of the various operations proposed for the radical cure of hernia from the earliest times down to the present, was then given.

The paper proper concluded with the following remarks :

"The ligature of the sac at its neck, with suture of the pillars of canal and ring, may be considered an established surgical procedure ; still being a comparatively new operation, a discussion of its merits will be of practical value in leading to further improvements, and with them permanent success of the operation. With the present lights before us, the most important point in the operation appears to be closing the neck of the sac as high up as possible, so as to effectually seal up the opening into the abdominal cavity. To do this completely it is necessary that the sac should be carefully separated from the adjacent tissues, and this is not always an easy matter, since oftentimes the true sac is obliterated and a new sac formed in the fibrous tissue, with the vascular and nervous distribution blended in such a manner as to render the dissection most difficult, if not impossible. In such a case MacEwen's operation could not be performed, and it would be impossible to twist the sac as recommended by Mr. Ball. This objection does not obtain in crural and umbilical herniæ, still since inguinal is the most frequent of the herniæ, it is of importance in them. In congenital cases, it is much easier to separate the sac and hence more possible to do a complete operation ; but since in young children, the truss properly applied and long continued, until the abdominal parietes have been so developed as to increase the obliquity of the canal, will in most instances produce a permanent cure, all operative procedures in children should be considered unwarrantable. In those cases, however, where an imprisoned testicle complicates the condition, the operation is unquestionably proper and the removal of the testicle justifiable, and for the simple reason that the presence of the gland in the canal predisposes to the descent of the hernia.

Since the main point in the success of the operation appears to have been the proper disposal of the sac it is not astonishing that operators who have given it their attention should have adopted diverse methods, each one of which has the same end in view. Whilst Ball twists it, MacEwen tucks it up ; Hardee insists upon the importance of inclosing the transversalis fascia with the sac in the ligature ; J. D. Bryant splits the pillars on either side and weaves in the sac ; Annandale opens the canal, ties the sac, cuts it away and stitches the opening ; on the other hand Stokes opens the sac and then stitching the neck, the canal and the pillars together, he leaves the sac in position ; Banks opens the sac, ligates the neck,

cuts away the fundus and sutures the pillars ; Alexander, of Liverpool, opens the canal, ligatures the sac flush with the peritoneum internally, then divides the neck below the ligature, leaving the sac in the canal without suturing the ring ; MacCormac advocates this plan, while Buckhanan cuts down to the sac, slits it up longitudinally on each side of the cord, divides the front part horizontally, rolls up the upper part, with which he plugs the internal ring and turns down the lower half to form the tunica vaginalis.

From a comparison of all the methods, it is apparent that no fixed rule of procedure is established, and although the radical operation is a marked improvement in the treatment of hernia, whether free or strangulated, we cannot consider it perfected, because the methods hitherto resorted to have not proved radical in results. The operation is ideally correct, but the question arises, whether, with the uncertainty of success, the risk justifies the operation, especially so if the circumstances of the individual are such that he can content himself with the use of a properly adjusted truss.

DR. M. H. RICHARDSON, of Boston : My experience with the operation for the radical cure of hernia has been small. Sufficient time has not elapsed to permit us to say what the ultimate result will be. My preference has been for the invagination of the sac as proposed by MacEwen. I do not advocate the operation in trivial cases of hernia. Here I believe that the application of a well-fitting truss is the most conservative and better plan.

DR. D. HAYES AGNEW, of Phila. : We have to yet speak with a good deal of reserve as to which is the most successful operation. Sufficient time has not elapsed to enable us to speak positively upon this subject. The operation which seems to me most applicable is that in which the sac is ligated, pushed into the internal ring, stitched there, and transverse sutures passed across the canal. I think that the omentum will constitute an important element in the radical cure of hernia. I believe that in all cases of strangulated hernia we are justified in attempting the radical cure. The same is true in those cases of hernia which cannot be controlled by a truss leaving the patient exposed to great risk.

DR. W. W. DAWSON, of Cincinnati : In cases where life is not in jeopardy we should approach the operation with a great deal of consideration. I have seen very different results from the same operation performed with equal care in cases apparently similar. Where life is in danger, duty impels us to operate, but where the question is one of æsthetics or abridged usefulness, the operation should be approached cautiously.

DR. L. McLANE TIFFANY, of Baltimore : My operation for radical cure in cases of strangulated hernia are more successful than formerly, and I

attribute this to the fact that I operate now in a more cleanly manner. I think that no operation for strangulated hernia is complete unless an attempt at radical cure is made. When the hernia is not strangulated, the question arises as to the kind of hernia, the inconvenience that it causes, and the circumstances of the individual. I do not believe that the operation, *per se*, is likely to be followed by much trouble. The method to be employed must be determined by the peculiarities of the case. In regard to children, I think in congenital hernia, especially where it is probable that the child will have to work for its living, that it is the duty of the surgeon to operate. Here it is not necessary to open the peritoneum. A ligature is thrown around the sac above and another lower down, and the intervening portion excised, forming a tunica vaginalis below and a peritoneal sac above.

DR. D. A. YANDELL, of Louisville: I believe that in strangulated hernia the surgeon should attempt the radical cure. This has been my practice and I have used various methods. It is difficult for any one man to decide which is the best operation, but in the course of ten years we shall be able to arrive at some opinion. At present it is simply historical and no one can say which is the best method.

DR. J. FORD THOMPSON, of Washington: So far as my experience has gone, I think there is very little difference in the operations. The main point is to get rid of the sac. I think that suture of the pillars is useless. The operation that I have employed is practically that of McBurney. In strangulated hernia it seems to me that there must be danger in inverting the sac as in MacEwen's operation. I have seen many cases of hernia in children, but I have never been able to adopt the view of Dr. Tiffany. As a rule, if we can keep the intestine reduced, the hernia is cured in a comparatively short time. In some cases of large hernia in children the radical operation is probably justifiable.

DR. W. W. KEEN, of Philadelphia: We doubtless all agree that in strangulated hernia no operation is complete without an attempt at radical cure. We also agree that in those cases where the hernia is not controlled by a truss and the patient is unable to labor, radical operation is advisable. The tendency at the present time is to extend the limits of the operation beyond these two classes. The presence of hernia is always attended with risk; hence the tendency at present is to operate on a larger number of cases. In children if the retentive measures after a thorough trial for a few years fail to effect a cure, I should be inclined to operate. In very large hernia, I should not be inclined to use MacEwen's method. The life of the sac is imperilled by separating it. In large hernia a certain amount of preparatory treatment is desirable to accustom the abdominal cavity to

the presence of the intestine, and thus prevent undue pressure upon the diaphragm and strain upon the sutures. In the more ordinary cases I think that the operation of McBurney is the best. I should place the operations in the following order: McBurney's, MacEwen's, and Ball's.

DR. C. H. MASTIN, of Mobile: I have little to add. The object of my paper was to elicit discussion as to the best method of operating. I have performed 34 operations for hernia, with 3 deaths. Two of these may be excluded, as the patients were *in extremis* at the time of the operation. This leaves 32 cases, with 1 death. Of this number there have been 8 radical cures. One of these cases I have watched for seventeen years. The method employed was after the sac was opened to pass a deep pin through the pillars, with an ordinary twisted suture over it, close the incision and place the leg on a double-inclined plane. Thirty-one cases have recovered with primary union. I believe that the cure is produced by the dense cicatricial tissue formed in the canal.

DR. J. R. WEIST, of Richmond, Ind.: I have operated on strangulated hernia 41 times. In 30 cases I have attempted to make a radical cure, using a variety of methods. In only 4 cases have I succeeded in keeping the hernia in. A number have remained well for six months to two years, and then the hernia has reappeared as bad as ever.

DR. M. H. RICHARDSON, of Boston, read a paper on

THE SURGICAL TREATMENT OF GANGRENOUS HERNIA.

The principal question discussed was the relative advantage of immediate excision and suture of the bowel, and the formation of an artificial anus, with subsequent closure. The views of various authorities were first quoted. The author then briefly reported the cases coming under his own observation.

Case 1.—A young woman with right femoral hernia, strangulated for one week. Bowel was found gangrenous and excised. Death from shock the next day.

Case 2.—Woman, *æt.* 65 years. Left inguinal hernia. On opening the sac the bowel was found strangulated and dark in color. The hernia was reduced, but the symptoms of obstruction continued, and five days later the sac was opened and the intestine found strangulated by a band within the ring. The bowel was drawn out, the strangulated portion excised and the ends sutured. The patient died of shock.

Case 3.—Woman, *æt.* 42 years. Had been treated by Christian Scientists for five days. There was a large umbilical hernia, with gangrenous intestine. The sac was filled with fecal matter. The constriction was found and the bowel drawn out and excised beyond the constrict-

tion and the ends united. This patient recovered perfectly and has remained well.

Case 4.—A woman with enormous umbilical hernia, with strangulation and gangrene. The faecal abscess opened by natural processes and the woman has been in perfect health since, with the exception of the artificial anus. This will be operated on next week.

In the two cases of excision the time required for the passage of the sutures was twenty minutes; the whole operation did not exceed one hour. The longer the operation the more are the chances reduced.

Reference was then made to the use of the bone plates of Senn and the catgut rings of Abbe. These devices may do more in these cases than anything else. Every case must be decided on its merits. The danger to life of resection in suitable cases is probably not greater than the danger of artificial anus with the dangers attending the subsequent closure of the same. The danger of the latter operation is especially great where the opening is near the stomach. Artificial anus is also objectionable on account of the excoriation of skin which attends it, and also the risk of giving way of the sutures.

The author concluded as follows: It seems to be the general opinion of surgeons everywhere that, under some circumstances, excision and suture are justifiable. It seems to me that the primary operation should only be done where all the conditions are favorable. It is preëminently a hospital operation. Every appliance and preparation should be ready for its most perfect performance. It is not an operation to be recommended to the general practitioner or to the unqualified operator. It depends for success more often upon rapid and skilful execution than almost any other operation.

There is no doubt that in some cases this procedure is imperative, where the part necrosed is too high up for intestinal nutrition to be maintained. The difficulty, of course, is to recognize this state of things. Even when it can be demonstrated that the jejunum is gangrenous, excision is not justifiable unless the patient's condition offers some hope, and there is a chance that the relief of the symptoms of obstruction may be followed by sufficient improvement to make a second operation unnecessary.

DR. D. HAYES AGNEW: My experience is too limited to enable me to say much upon this subject. I recall three cases of gangrenous hernia. One was a case of inguinal hernia in which I excised a portion of the bowel. The patient recovered from the immediate effects of the operation and passed out of my hands. Some months afterwards, he was advised by another surgeon to apply a compress to the external opening so as to compel nature to establish a communication between the two portions of bowel. He did so with

fatal results. The second case was one of femoral hernia which had lasted six or seven days. It was laid open and the patient recovered. As the granulations filled the opening, communication took place between the two portions of bowel. The third case was one of umbilical hernia. I opened the sac, excised 10 inches of intestine and carefully stitched the ends. The patient died of hæmorrhage at the end of two days. It occurs to me that it would be wise, in such a case, to stitch the intestine to the skin and at a subsequent period do this operation of Dr. Abbe.

DR. WILLIAM T. BRIGGS, of Nashville: Although I have seen many cases of strangulated hernia, I have seen but three instances of gangrenous intestine. In the first case I opened the abscess and the faecal contents escaped. The patient lived some time, but died of inanition. In the second case I attached the bowel to surrounding parts and made an opening into it. The patient died in twenty-four hours. The third case I left entirely to nature and the patient recovered with an artificial anus.

DR. P. S. CONNER, of Cincinnati: I have had three cases of gangrenous hernia and have seen a fourth in the practice of Dr. Dandridge. The operation of intestinal anastomosis is valuable. It can be performed rapidly, it is simple and establishes the continuity of the intestinal tract more perfectly than any other operation that has been suggested.

DR. W. F. PECK, of Davenport: From my experience, I think that great benefit in the way of prevention would result from educating the subjects of this trouble in regard to the dangers of hernia and the way of reduction.

DR. J. EWING MEARS, of Philadelphia: I have had two cases; one of umbilical hernia in which I made an artificial anus, the other of femoral hernia where I performed resection and returned the intestine to the abdomen. Both resulted fatally inside of forty-eight hours. A surgeon of Vienna has suggested that in these cases the gangrenous intestine be withdrawn from the abdomen and held in place outside by a tampon of iodoform gauze. In this way the intestine can be kept under observation and treated as seems best.

DR. W. W. KEEN, of Philadelphia: I think that the introduction of the method of intestinal anastomosis by the bone plates of Senn or the catgut ring of Abbe is a great advantage over former methods. The mortality following this method is greatly less than that following reunion of the ends of the bowel.

DR. T. A. MCGRAW, of Detroit: I have heard nothing in regard to the pathological condition of the bowel above the seat of stricture. In some cases the bowel is healthy immediately above the point of strangulation, while in others the inflammatory process extends 6 to 10 inches above the point of constriction. This must make a great

difference as regards the results of operation.

DR. A. VANDERVEER, of Albany: Eleven years ago I saw a case of gangrenous inguinal hernia, but the condition was so bad that nothing was done. The patient died a few hours later. Two years ago I saw a similar case, except that the patient was younger and the collapse not so great. I opened freely and left it to nature. The man recovered with an artificial anus.

DR. H. H. MUDD, of St. Louis: I think that gangrenous hernia is not so rare as seems to be the general impression. I can recall at least seven cases. Three of these cases occurred more than four years ago and all died. During the last four years I have operated on four cases, excising a portion of bowel, with recovery in one case.

(To be concluded.)

Philadelphia County Medical Society.

Stated Meeting, March 27, 1889.

THE PRESIDENT, S. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. W. W. KEEN read a paper on

UNCOMPLETED NEPHRECTOMY.

(See page 762.)

DR. DEFORREST WILLARD: I was unfortunately detained, and did not hear Dr. Steinbach's paper, but I understand that in his case the abdominal incision was employed. In Dr. Keen's case the lumbar incision was employed at the operation, but that at the post-mortem an attempt was made to remove the kidney by an abdominal incision in the semi-lunaris. I do not consider that this question in regard to the incision to be employed, is yet settled. As a rule, however, the anterior median method offers better opportunities for diagnosis, for examination of the other kidney, and for safe removal. In cases where a stone is suspected, or the presence of pus is probable, the lumbar incision is certainly proper, the operation may be simply a nephrotomy, and not a nephrectomy, and then we have better drainage. In simple purulent kidney, it is better to secure drainage and not remove the kidney. The results, so far as life are concerned, are better by this method. In tuberculous kidneys, the results of nephrectomy have been more satisfactory. In Bardenhauer's statistics,¹ numbering some thirty-five nephrectomies, where twenty-five were for purulent kidney of various forms, the mortality was not much higher than ordinary nephrectomy. Out of thirty-five cases he lost ten.

The choice of the incision will depend largely upon the condition of the case, and upon the

diagnosis. Many nephrectomies have been performed after the abdominal incision has been made for other purposes, as when the ureter has been cut in laparotomy. I do not know why it is any better, but Schmidt recommends that in such cases the kidney be removed by the lumbar incision. It seems to me that this would decidedly delay the operation, and would be more likely to cause contamination of the abdominal cavity. I do not think that the results are much more serious in the anterior operation than they are in the posterior.

My practical experience has been limited to two cases, one for gunshot wound, and the other for a tuberculous kidney, but in both I employed the anterior median route. In the first case there were evidences of wounds of other organs. In the latter case the kidney was pushed far anteriorly, and I thought the abdominal incision the better one.

The difficulties of the lumbar operation are certainly much increased where there is only a short space between the twelfth rib and the crest of the ilium. In Dr. Keen's case he found it impossible to reach the hilum; if he had employed the median incision at the post-mortem operation, instead of the incision through the linea semi-lunaris, he would have been able to have reached it without difficulty.

In regard to the sutures to be employed in *nephrorrhaphy*, I think that the failures have resulted from the use of catgut. We must employ a permanent suture, which will hold for a long time, and anchor the kidney until it is thoroughly fixed in its position. The question of decubitus is of importance. A month is the shortest possible time we can expect any fixation. The use of pads is very unsatisfactory. We are obliged to apply the pad upon the abdominal walls to an organ that lies deep in the loins with the intestines in front of it. We cannot hope to hold it in position by any such means. Therefore the dorsal decubitus should be maintained for a long time.

DR. M. PRICE: The case of Dr. Steinbach is certainly a very interesting one, and I see no other course save that which he tried, of operating by the abdominal method. Even in Dr. Keen's case, where he states that the first idea was an exploratory operation, I think that the anterior method would have been better. I think it is the better plan, even if after making the diagnosis you close the abdominal incision and remove the kidney by the lumbar method. An incision one and a half inches in length affords ample room for the examination of all the organs. I have twice examined both kidneys through such an opening. In one case of supposed gallstones, I found the viscera attached to the abdominal wall. After separating them, I examined the kidneys without difficulty, and found them in

¹Berlin. Klin. Woch., October 15, 1888. Philadelphia Medical News, December 1, 1888.

good condition. In the case where I removed the kidney, I had no difficulty in feeling both kidneys through a small abdominal incision. I think that if Dr. Keen had made the median abdominal incision, and found the kidney so seriously diseased, he probably would not have made as great an effort as he did through the lumbar incision.

Dr. Steinbach, in his report, does not state whether or not he used drainage. My impression is that the anterior route is the best for drainage, which, in these cases, is of paramount importance. So much tearing is done in releasing the kidney that drainage for twenty-four or forty-eight hours is necessary, or at least can do no harm. I do not believe that any drain answers its purpose so well as one that can be cleaned by the attendant or nurse. The best method to stop oozing of blood is to keep it cleaned away. Keep no blood in contact with the bleeding vessel.

I consider the danger no greater by the anterior than by the posterior method. It is the only method to employ in cases of gunshot wounds.

In regard to the use of morphia, I differ from Dr. Steinbach, unless he had made up his mind that the patient was going to die. I believe that morphia has a tendency to cause suppression of urine. It also lowers the vitality and assists in killing the patient. I should not think of using morphia in abdominal cases unless the patient were dying. Where morphia has been used in surgery, and especially in abdominal surgery, I have had cause to regret it.

DR. JOHN B. DEEVER: I may say a word in regard to the choice of incision. I have operated both by the abdominal and lumbar method. I consider that the anterior incision is preferable in cases of solid growths, particularly where they have reached any size. We run greater risks in attempting to break up the adhesions to the capsule by the lumbar incision, where we cannot see what we are doing, than we do through the anterior incision.

The proper course is, I think, to go through the linea semilunaris. This brings us nearer to the organ, and gives a better opportunity to work to the outer side of the colon, which is important, as the blood-vessels are in relation to the internal layer of the meso-colon, and not with the external layer.

In cases of liquid accumulations in the kidney, I do not think that we operate with quite as much facility anteriorly as posteriorly. The lumbar incision affords better opportunities for drainage under these circumstances, but drainage can be satisfactorily accomplished by the anterior method by the glass drainage tube.

The abdominal incision affords us better opportunities for the examination of neighboring organs. For purposes of diagnosis it is more satisfactory than the operation through the loins.

There is no doubt that nephrorrhaphy the

proper form of suture is antiseptic silk. I know of one failure resulting from the use of catgut. It is probably impossible to pass sutures through the capsule of the kidney without also involving the substance of the organ, yet I think if we could avoid wounding the kidney it would be better. I have no doubt that the appearance of albumin in Dr. Keen's case after the operation, was due to the sutures.

In regard to the meso-nephron, I have seen several cases of floating kidney in the dissecting-room, and I have yet to meet with an instance of a reflection of the peritoneum which could be called a meso-nephron. While I would not differ from so distinguished an authority as Dr. Morris, yet I have not met with this condition.

The question of removal of solid growths of the kidney is largely influenced by the age of the patient. It is almost useless to operate for carcinoma of the kidney in early life or in late life, so that the middle period offers the best chances for a favorable result in these cases.

DR. THOMAS R. NEILSON: In looking over the literature of nephrectomy, one is struck by the variableness of operators as to the method chosen to reach the kidney; and the remarks that have been made to-night clearly illustrate this. One writer will prefer the lumbar incision another will select the abdominal method, while a third will use either plan, and yet in all the instances the disease may seem to be about as extensive and the size of the kidneys may be the same. A great deal depends upon the choice of the operator, as well as upon the condition and proportions of the patient.

The statistics of the removal of the kidneys for malignant disease are so unfavorable that any operation seems to be almost hopeless; nevertheless, I do not think, that in individual cases, this should be a contra-indication if the operation seems to be justifiable on other grounds. In children, the statistics of Dr. Gross, in 1885, were that in thirteen operations only four recovered from the operation, and these subsequently died from return of the disease elsewhere.

In operating in cases of wound of the kidney, it would seem to be guided by the position and extent of the wound. If the wound involves the abdominal viscera, no one would hesitate to open the abdomen. On the other hand, if there were any doubt, the course of the wound should be followed and the kidney reached and explored. If there are marked signs of hæmorrhage, the operation should be performed at once. Even if the hæmorrhage is retro-peritoneal, it may be assumed that, sooner or later, the clot will by pressure force its way through the peritoneum and cause septic peritonitis. Careful exploration and thorough drainage in these cases is absolutely requisite. In subparietal wounds of the kidney, if operation be necessary, it would seem that the

only choice is the lumbar incision. As illustrating the tolerance of the kidney for a certain degree of injury to its substance, a point to which Dr. Keen has called our attention, I may mention the following case: Some years ago I saw, at the Episcopal Hospital, a man who was brought in with a large hæmatoma of the back, the result of being struck in the loin by the buffer of a locomotive. He recovered without operation. A year later he returned to the hospital with symptoms of stone in the bladder. At the operation instead of a stone, there was found a spicule of bone, one-fourth of an inch wide, and one-half or three-fourths of an inch long. I assume that there had been a fracture of one of the lower ribs, a fragment of bone being driven into the kidney or its pelvis, and later finding its way into the bladder.

DR. HENRY F. FORMAD: I rise to protest against the rather loose pathological nomenclature in regard to malignant disease of the kidney. We hear of cancer of the kidney and of sarcoma of the kidney. Alveolar sarcoma and cancer are used synonymously. This is Virchow's view. According to modern views all of these things are sarcomas. Again, there is no such thing as epithelium in the kidney. There is only epithelium which cannot give rise to cancer.

It is a true mesoblastic growth which can only give rise to sarcoma. We can take for granted that all of these cases reported as cancers are sarcomata.

In sarcomata there are sometimes hæmorrhagic infarctions which give rise to indurated masses, and on section give to the growth the book appearance of cancer.

It is a well-established fact that tumors of the kidneys and of the suprarenal bodies will not encroach upon surrounding structures. They do not cause metastasis; so that removal of the diseased kidney to prevent the spread of the disease is unnecessary. In view of the bad statistical results, I think it would be better if these cases of malignant disease of the kidney were let alone.

I have a point to make in regard to floating kidney. I began to record the occurrence of floating kidney, having pretty good opportunity to do so. I was so successful that every day I found a floating kidney. I began to investigate and I found that every woman had a floating kidney. The right kidney of nearly every woman is so loosely attached that floating kidney on the right side is a normal condition in woman. Actual floating kidney is merely a question of degree. When you attempt to reach the right kidney in autopsies on women it is difficult to find it, as it is never in the same place. It never lies in close proximity with the liver as in man.

DR. WILLIAM J. TAYLOR: I had the pleasure of assisting at the operation of Dr. Keen and would emphasize the fact of the tremendous

hæmorrhage, and also the extreme density of these calcareous masses. They felt exactly like a stone.

DR. JAMES TYSON: I would say a word with reference to the etiology of floating kidneys. I have had a number of such cases under observation. In searching for the cause, I have been compelled to conclude that in the majority of instances it is congenital, and what has been stated by Dr. Formad serves to strengthen this view. I have seen most typical instances of floating kidney in men, and I have seen it more frequently in women who have never borne children than in those who have had children. Even in those cases where it is supposed to have been caused by accident, I think that in all probability the condition has been congenital, and, if anything, only exaggerated by the fall.

In regard to the treatment of floating kidney by the use of pads, etc., I have had surgeons in consultation in cases of this kind, and I have never seen any advantage result from such devices.

DR. WILLIAM HUNT: I have recorded a case in which a fast kidney was found in the wrong place, which might confuse an operator cutting for the organ on account of symptoms. Some years ago, I made a post-mortem at the Pennsylvania hospital on a man who had died of concussion of the brain, in which I found the left kidney, enveloped in its capsule, lying upon the fourth and fifth lumbar vertebræ and partly covering the promontory of the sacrum. The sigmoid flexure passed along its outer and superior edges, while the rectum ran along the inner edge and from thence down the middle line of the sacrum. The emulgent vessels entered from above through a fissure in the kidney, leading diagonally from the superior edge to the pelvis.

The pelvis of the kidney and the ureter were normal, though of course the latter was shorter than usual. The sigmoid flexure embraced the kidney in its folds.

DR. J. M. BALDY: As regards the relative value of the lumbar and abdominal incision, the abdominal seems to me to present several points of advantage. Through the abdominal incision both kidneys can be reached with little difficulty. In all these troubles it is important that the second kidney should be examined, if the removal of one is contemplated. Where the lumbar incision is adopted this is, of course, impossible, and the difficulties of examining even the diseased kidney are well shown by the case under discussion. In the abdominal operation, the condition of the kidney could be determined, and just such accidents as happened in Dr. Keen's case—the stripping off of the capsule and the dangers of hæmorrhage and shock—would be averted.

There is great importance in drainage. A tube that can be kept clean, is the drainage tube *par excellence*—the glass tube is such.

In one case of malignant disease, in which I witnessed the removal of the kidney by the abdominal incision, the hæmorrhage not being entirely controlled, the peritoneal cavity was entirely closed off from the bed of the kidney by stitching the cut edges of the peritoneum together; prior to this, however, a counter-opening was made through the muscles of the back, and thus good drainage secured. Patient made a good recovery.

DR. JOHN B. ROBERTS: I wish to refer to a case of cure of movable kidney without operation. I had a boy, 7 years of age, referred to me four years ago by Dr. M. O'Hara. At irregular intervals the patient was seized with severe pain in the left side of the abdomen, and with this there was the appearance of a tumor in the hypochondrium and total suppression of urine. Various theories had been held to explain the condition. The only conclusion that I could reach, though this was not shared by Dr. O'Hara, was that the boy had a floating kidney, and that at the times of the paroxysms the ureters became twisted, causing the suppression of urine and the intense pain. The boy never had any pain or trouble with the urine except when the tumor was felt. At my suggestion Dr. O'Hara had made a pad which pressed against the left hypochondrium. This was worn for a short time. The boy then passed from my notice, but I learned a few days ago that he had perfectly recovered. There is, of course, in this case an element of uncertainty in regard to the diagnosis. When I looked into the literature of this subject, I was surprised to find how much stress was laid upon the possibility of the ureters becoming twisted, and the flow of urine being interfered with.

I wish, in connection with the question of the lumbar incision, to refer to an accident which I had in an attempt to explore the kidney for a supposed renal calculus. After making the incision down to the kidney, I determined to enlarge it a little. The diaphragm hung down in a fold and was readily seen. I made my incision a little longer in the upward direction, and made a minute perforation in the diaphragm where it is attached to the spinal column. There was a loud whistle as the air rushed into the pleura. I put in a suture and closed the opening, and no harm was done; but for a few days the patient insisted that the bandage was too tight, because he could not breathe freely. The pain which the patient had felt disappeared after the operation, although no stone was found. He went home before the wound had closed, and a number of months later died of some obscure disease.

It is important to recollect, when operating close to the vertebral column, that the posterior attachment of the diaphragm near the middle line extends further down than might be realized from watching its loose muscular curtain exposed in the wound.

DR. G. G. DAVIS: Dr. Formad seems to characterize all these growths as alveolar sarcoma. In primary growths of the kidney this may be correct, but such a statement gives one the idea that there is a sameness about these growths which is not the case. The tumor presented by Dr. Keen has the macroscopic appearance of scirrhus. In other specimens the growths may be smooth, resembling sarcoma found in other parts of the body. The macroscopic appearances of these tumors are decidedly different. When it is said that all growths of the kidney are alveolar sarcoma, I think that a mistake is made. Is not the kidney subject to secondary growths? We have an illustration of this in the case of Dr. Grove's. In his case, the first manifestations at least were in the axilla. In the report of the microscopical appearances, I did not hear the term alveolar sarcoma used. The disease of the kidney was what is commonly known as melanotic sarcoma. It was not supposed that the organ was the seat of a growth peculiar to the kidney.

DR. HENRY F. FORMAD: I did not mean to say that all tumors of the kidney were alveolar sarcoma. We have other forms of sarcoma, but what is commonly called cancer is alveolar sarcoma. Secondary growths of any character may occur, and even cancer may be secondary; but it will be only an insignificant part of the general disease.

DR. S. SOLIS-COHEN: The administration of morphia in these cases has been referred to. It is extremely dangerous to use morphia in any case in which the kidney has been treated surgically. I have seen several medical cases in which the use of morphia has produced suppression of urine. This point should be borne in mind by surgeons in the treatment of these cases.

DR. STEINBACH: I had expected criticism in regard to the diagnosis of my case, but nothing has been said on this point, and I therefore have little to reply to. Reference has been made to drainage. I was prepared to drain, but there was practically no hæmorrhage, and the whole procedure was perfectly clean, so that drainage was not required.

The dose of morphia given was very small, and was given without my personal knowledge. We have a house mixture containing small quantities of bromide and morphia. One dose of this was administered by the house physician. I do not use morphia after other surgical operations, and certainly would not use it in such cases as this unless strong indication existed.

DR. W. W. KEEN: I think that there is no doubt that in the case of a large tumor of the kidney, particularly a large solid tumor the size of which cannot be diminished by tapping, the position taken by several of the speakers is correct—that the anterior incision is the proper one. Where there is a small growth, or a stone in the

kidney, or the operation is an exploratory one, I cannot think that the anterior incision is the best. Statistics certainly show that the lumbar incision is attended with much less risks than the anterior. Where there is no reason to suppose that an unusual amount of room will be required, I think the lumbar incision is the proper one to employ.

It has been also suggested that possibly the anterior incision, in the present case of nephrectomy, would have given so much information that I should have decided not to operate. I do not think that I should have reached any such conclusion, for it was not the character of the growth, but the adhesions at the hilum that interfered with the removal of the organ, and these could not have been determined until the operation was in progress. I think that it would have been as impossible to remove the kidney by the one method as by the other. I had the pleasure of seeing Dr. Steinbach's case, but only for a moment just prior to the beginning of the operation, and I certainly was convinced that it was a case of enlarged gall-bladder with gall-stones. The slightest movement caused a grating of one stone upon the other. The tumor was in the position of the gall-bladder. I never before saw a kidney so displaced. The long axis, instead of being vertical, lay in an antero-posterior position, and the upper end of the kidney occupied precisely the position of the gall-bladder. The steps of the operation have been well described by Dr. Steinbach, and I have nothing to add. The mistake in diagnosis, under these circumstances, was very natural.

BOOK REVIEWS.

ELECTRICITY AND THE METHODS OF ITS EMPLOYMENT IN REMOVING SUPERFLUOUS HAIR AND OTHER FACIAL BLEMISHES. By PLVM. S. HAYES, A.M., M.D. Chicago: W. T. Keener.

The author has given the profession this little volume of 128 pages setting forth the subject in clear and concise language. In regard to the use of electrolysis in the removal of hair we learn that it has stood the test of not less than thirteen years and still stands as the most efficient means to be employed for this purpose. The book answers all possible inquiries that might arise in the mind of one interested in this subject, but still it does not hesitate to state that in no operation where human life is not involved does experience count for more than in this comparatively simple and easily executed procedure. We note that the author's ten years' experience in this use of electricity has taught him to anticipate the weakness of his fellow practitioner, whose mind is early reassured by the statement that he need know

nothing of the theory of electrolysis, but that he must understand that the galvanic current is the only one to be employed. And finally, under the admonition of a series of "Don't's," he says: "Don't attempt to use the faradic current for electrolysis." Would anyone think of doing so who had at any time in his life read a work on elementary physics, such as is in daily use in the common schools. We certainly hope he would not; and yet, however much we dislike this intimation against the learning of the medical profession in a branch of elementary science, we must, nevertheless, bear it, for facts seem to justify it.

If all books which are written for a presumably scientific body, *i. e.*, the medical profession, were written in a thoroughly scientific manner, utterly ignoring the wants of the untutored, it would be infinitely better, not only for that profession, but for their literature.

F. H. M.

HANDBOOK OF THE DIAGNOSIS AND TREATMENT OF THE DISEASES OF THE THROAT NOSE, AND AND NASO-PHARYNX. By CARL SEILER, M.D., Instructor in Laryngology and Lecturer on Diseases of the Upper Air Passages in the University of Pennsylvania, etc. Third Edition, thoroughly revised and greatly enlarged. With 2 lithographic plates containing 10 figures, and 101 wood engravings. 8vo, pp. xii—573. Philadelphia: Lea Brothers & Co. 1889. Chicago: A. C. McClurg & Co.

The author is a careful observer and a concise and accurate relator, and, rarer still in medical authorship, a master of the difficult art of omission. The result is a handbook which will be read throughout with pleasure and profit by thousands, to whom the more exhaustive treatises are of service for occasional reference only.

Much space, proportionately, is devoted to the anatomy and physiology of the upper respiratory passages, and to laryngoscopic and rhinoscopic technique, including the various methods of electrical illumination. Preference is accorded to the electric incandescent light, which has been made available even to those not upon a regular light circuit, by the introduction of storage batteries, one of which, suitable for this purpose, is figured and described.

A new chapter on acoustics, voice production, and articulation, imparts a halo of originality to this part of the volume and is especially acceptable, inasmuch as the author is known to be one of few laryngologists qualified to discourse on this part of the subject.

No one section better illustrates the general character and scope of the work than that on "Hypertrophy of the Tonsils," in which three varieties are described, the ordinary soft tonsil of childhood; the scirrhus tonsil of young adults; and the so-called ragged tonsil. So much nonsense

has been informally promulgated concerning the operation of tonsillotomy that we quote the following passage from this authority: "The best and most satisfactory way of treating hypertrophied tonsils is to cut them off as close to the pillars of the fauces as possible," which calls to mind also a recent dictum by Mr. Lennox Browne, "Chronic enlargement of the tonsils is only to be treated satisfactorily by the one method of excision, and there does not appear any valid reason why there should be two opinions on the subject." This author recommends the tonsillotome for the soft tonsil and the cold-wire snare, to avoid hæmorrhage, for the scirrhus variety. Cautery-puncture is advised only for the ragged tonsil. Total extirpation or enucleation is both unnecessary and dangerous.

The ordinary forms of chronic pharyngitis such follicular pharyngitis and pharyngitis sicca are summarily dismissed as symptomatic expressions of pathological states elsewhere. It were better even as symptoms to give them more extended notice.

"Functional Disorders of the Larynx," "Laryngeal Neoplasms," "Atrophic Nasal Catarrh," and "Hay Fever," are intelligently summarized, while "Catching Cold," "Clergyman's Sore Throat," "Laryngitis Phthisica," "Chronic Nasal Catarrh," and "Tumors in the Nasal Cavities," are adequately treated and embody many original views and valuable suggestions.

W. E. C.

MISCELLANY.

THE MEDICAL SOCIETY OF NEW JERSEY will hold its next annual meeting in the Coleman House, at Asbury Park, on June 18 and 19, 1889, commencing at 4 P.M. of Tuesday, June 18. President, H. Genet Taylor, M.D., Camden; Secretary, William Pierson, M.D., Orange, N. J.

THE NORTH TEXAS MEDICAL ASSOCIATION will hold its next semi-annual meeting in the city of Paris, Texas, beginning Tuesday, June 11, 1889, and continue its sessions for three days. The meeting will be called to order promptly at 3:30 o'clock, P.M. In addition to the subjects announced in the programme many interesting volunteer papers have been promised. It is requested that every one who may have a contribution for this meeting will upon his arrival promptly hand the title of his paper and his name to the Secretary, Dr. Geo. R. Clayton, so that it can be properly classified in its appropriate Section and come up in its regular order. The meeting in Paris promises to be one of the most attractive and successful the Association has ever enjoyed. Some distinguished visitors are expected to be present.

LETTERS RECEIVED.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from May 18, 1889, to May 24, 1889.

Major William H. Forwood, Surgeon, leave of absence granted on surgeon's certificate of disability, in S. O. 35, Dept. of Dakota, April 8, 1889, is extended one month on surgeon's certificate of disability, by direction of the acting Secretary of War. Par. 13, S. O. 118, A. G. O., Washington, May 22, 1889.

Major Passmore Middleton, Surgeon, will, as soon as practicable after his arrival at Ft. Trumbull, Conn., proceed to Ft. Warren, Mass., and report for temporary duty until the return of the post surgeon from detached service with batteries of the Fourth Artillery ordered to Atlanta, Ga. He will then return to his proper station (St. Francis Bks., Fla.). Par. 2, S. O. 113, Hdqrs. Div. of the Atlantic, Governor's Island, New York City, May 18, 1889.

Capt. Aaron H. Appel, Asst. Surgeon, leave of absence granted in S. O. 38, Div. of the Missouri, April 16, 1889, is extended twenty days, by direction of the Secretary of War. Par. 2, S. O. 114, A. G. O., Washington, May 17, 1889.

Capt. William Stephenson, Asst. Surgeon, granted leave of absence for four months, with permission to go beyond sea, by direction of the Secretary of War. Par. 15, S. O. 114, A. G. O., Washington, May 17, 1889.

First Lieut. Ogden Rafferty, Asst. Surgeon, granted leave of absence for one month. Par. 3, S. O. 29, Hdqrs. Dept. of Texas, San Antonio, Tex., May 13, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending May 25, 1889.

P. A. Surgeon L. G. Heneberger, detached from the "Thetis" and ordered to the "Iroquois."

Asst. Surgeon F. A. Hesler, promoted to be Passed Assistant Surgeon in the U. S. Navy.

CORRIGENDA.

In the report of Dr. Wm. H. Welch's paper on "Hydrophobia," published in THE JOURNAL of May 18, occur the following errors: Page 601, col. 1, line 23 from top, read Zagari, instead of Lagari; p. 601, col. 1, line 21 from bottom, read milk, instead of neck; p. 601, col. 1, line 15 from bottom, read nerves, instead of nerve; p. 601, col. 1, line 13 from bottom, insert *only*, after multiplication; p. 602, col. 2, line 15 from top should read, "Dr. Welch collected from Pasteur's reports for 1887 and the first half of 1888," etc.

MEDICAL EDUCATION, AND THE LAWS REGULATING THE PRACTICE OF MEDICINE IN TURKEY.

BY THOMAS W. KAY, M.D.,

EX-SURGEON TO THE JOHANNITEL HOSPITAL BEIRUT, SYRIA.

While the present cry for higher medical education is going on, it may be profitable to consider what is being done in that line in other countries. The condition of medicine in England, France and Germany is well known to most of us; but we are comparatively ignorant of what is being done in Turkey, a country containing an area of about 1,700,000 square miles, and having some 45,000,000 inhabitants.

Its medical practitioners are derived from both native and foreign schools, the latter being represented by both Europeans and Americans. All persons holding foreign diplomas must present them at Constantinople to their respective consulates; where, if from reputable colleges, they are visé by the minister. They must then present themselves at the Imperial Medical School, and pass a colloquium in French or Turkish, or through an interpreter, before three or more of the professors, satisfying them that they are physicians, and the rightful owners of the diplomas.

The colloquium is short but thorough, and one is treated with the greatest respect. No distinction is shown between American and European graduates, though this is the only place in Europe where such is the case. The short and imperfect courses of many of our medical colleges are only too well known abroad, and as a consequence of this, the average American M.D. has little or no standing with European physicians. The American dentist, on the contrary, stands at the head of his profession all over Europe. The colloquium costs about \$35, and a permit is given which authorizes its holder to practice medicine in all parts of the Turkish Dominions.

More is required of Turkish subjects who return from America with medical diplomas, and they are obliged to pass as rigid an examination as the students of the Imperial School. In some cases a year or more must be spent in study before

they can pass. The justice of this distinction will be readily seen when we reflect for a moment on the requirements of the respective schools. Legally, no one can practice medicine in Turkey without a diploma or permit from Constantinople; but there, as in most countries, we find more or less bribery, and in many out of the way places the law is disregarded.

In the whole Turkish Empire there are only five institutions in which there is any teaching of medicine, and in only two of these are diplomas given.

The Imperial Medical school of Constantinople was founded in 1833 by the Sultan Mahmoud. It has a six years course, an average class of 450, and, since its foundation, has had some 1,400 graduates. The faculty consists of twenty professors, at the head of which is Dr. Marco Pasha, one well fitted for the important position he holds.

The Cairo School of Medicine is several years older than that of Constantinople, having been founded in 1827, under the reign of Mohammed Ali, at Abu-Zabel, from which place it was removed to Cairo. It has a preparatory course of one year, and a medical course of five years of eight months each. Its classes vary in size from 160 to 200, and its graduates average yearly about twenty. There is a Director, Dr. Issa Pasha Handy, and twenty professors connected with the Cairo School. Its diplomas can be used only in Egyptian territory and, should its graduates wish to practice in any other part of the Turkish Empire, they must first pass a colloquium at Constantinople and obtain a permit as in the case of graduates of foreign colleges.

The Syrian Protestant College at Beirut established a medical department twenty-two years ago, since which time it has graduated 105 students. There are five professors and a President, and its course is four years. The Government permits it to give only a certificate to its graduates stating that they have followed the regular course and have successfully passed their examinations. This, when presented at Constantinople, entitles its holder to an examination at the Imperial Medical College, after passing which he receives his diploma.

There are two other institutions which have tried, but in vain, to get some recognition for

their medical departments from the Government. They are the Central Turkey College at Aintab, and the Jesuit College at Beirut—both, like the Syrian Protestant College, missionary institutions.

All efforts aimed at the Mohammedan religion are aimed at the Turkish Government, hence she justly guards her country against all missionary institutions, but especially medical colleges, for the influence of the medical missionary is greater than any other.

The standard of medical education is set by the Constantinople School, and, as that has a six years course, all of the other colleges have practically the same, the discrepancy in time being made up for in the requirements for matriculation, so a description of one college will do for all.

Through the kindness of Drs. Grant-Bey and Issa Pasha Handy, of Cairo, I have succeeded in getting an accurate account of the Cairo School, so I will confine my remarks to this. A minute description of it by Dr. Grant-Bey will be found in the Arabic medical journal *U'sh-Shifa* for 1888.

This school was founded by Dr. Clot, a Frenchman—afterwards the famous Clot-Bey. After him, the position of Director was held successively by Perron, Chaffey-Bey, Griesinger and others. It was in Griesinger's time and at Cairo that Bilharz discovered the parasite bearing his name. At first, the lectures were delivered in French and translated into Arabic for the students, who studied the French language at the same time. The European professors have been gradually supplanted by natives, till now only one remains. At the same time text-books were being written or translated into Arabic, so that at present all teaching is done in that language. Since British influence has been so great in Egypt, a professor of English has been appointed; and each medical student, in addition to his own language, must have a knowledge of either English or French. The building for the School of Medicine is quite new, with all modern conveniences, and attached to this is, 1, a Museum of Pathological Anatomy; 2, Bacteriological Laboratory; 3, Laboratory of Practical Chemistry; 4, Laboratory for Microscopy; 5, Museum of Zoology and Comparative Anatomy; 6, Museum of Mineralogy and Geology; and 7, Collection of *Materia Medica*.

Near the medical building is a large hospital with an average of 400 patients, the clinics of which students of the second, third and fourth years are required to attend. Those of the fifth year are attached to the Hospital of qasr-el-Ainy, as externes and internes, while preparing for their final examinations.

In connection with the medical school is a school of pharmacy and a school of midwifery; the latter, however, because of social and religious prejudices, is lacking in practical training. The course for each of these schools requires four years for its completion.

All applicants for matriculation must be 16 years of age, and present certificates as to moral character and preliminary training, and they must pass oral and written examinations in Arabic, English or French, history, geography, arithmetic, cosmography, geometry, algebra, physics, chemistry and natural history.

Physics. This is studied in the preparatory year, 96 hours being devoted to didactic, and 192 hours to laboratory work. Chemistry is taught during the preparatory and first years, 96 hours being devoted each year to theoretical and practical work.

Natural history extends through the preparatory and first years, 96 hours being devoted each year to theoretical and practical work.

Physiology is taught the first and second years, during the first there being 96 hours of didactic, and 64 hours of practical work; and during the second year 96 hours of didactic and 192 hours of practical work. Micrography is also studied during the first and second years, there being 64 hours of didactic and 128 hours of practical work each year.

Anatomy extends through the first and second years, there being 96 hours of didactic and 192 hours of practical work each year. Each student is also required to dissect an entire human corpse his first, and the same his second year.

Pathological anatomy is studied during the third year, there being 128 hours of didactic and practical work.

Internal pathology is taught the third and fourth years, 96 hours being devoted each year to the subject, each student being instructed practically in the various modes of diagnosis, and the holding of autopsies. Surgery is taught during the third and fourth years, 96 hours being devoted each year to its study; the third year being chiefly didactic, and the fourth clinical surgery.

Operative surgery is taught the third year, there being 96 hours devoted to its theory and 64 hours to its practice. Each student must perform the operations on the cadaver and on the mannikin.

Materia medica is taught during the third year, 96 hours being devoted to the subject.

Obstetrics is taught during the fourth year, 96 hours being devoted to the didactical part and demonstrations on the mannikin. When cases occur in the hospital the students are required to be present.

Ophthalmology. Ninety-six hours are devoted to this during the fourth year, and are composed of lectures and demonstrations, most of the practical work being done at the hospital clinics.

Hygiene is also studied during the fourth year, having ninety-six hours devoted to it.

Legal medicine is studied the fifth year, 96 hours being spent in theoretical and practical work.

Pharmacology is also studied the fifth year, 96 hours being devoted to didactic and 192 hours to

practical work, the students having to assist in the pharmaceutical course. As yet, no chairs have been created for gynecology and pediatrics; the one being included under surgery, and the other under internal pathology.

Examinations are held at the end of each year on all that has been studied, and four final examinations are held at stated periods. These examinations are oral, written and practical; the student being required to examine and diagnose, in the presence of the examiners, two cases of internal disease, two cases of diseases of the eye, and two specimens of pathological anatomy with the microscope. Should he answer less than two-thirds of all the questions, or should he get zero on any one subject, he will be rejected.

The Board of Examiners for admission to the study of medicine is composed of the professors of the College, with four others appointed by the Minister of Public Instruction.

For the yearly examinations a Board of Examiners is chosen by the Government Medical Department and the Minister of Public Instruction, who act conjointly with the professors of the College. These examiners are chosen from medical men in the employ of the Government and private practitioners, all of whom have equal rights in voting, which insures a rigid and impartial examination.

Does not a system like this, in a country which labors under as many disadvantages as Turkey, put to shame many of our medical institutions in America?

TEMPERAMENT.

Read before the Denver Medical Association, and Arapahoe County Medical Society.

BY S. EDWIN SOLLY, M.D.,
OF COLORADO SPRINGS, COL.

What is it? To most of us it is a certain though ill-defined factor to be reckoned with in our dealings mental or physical with our fellow man.

In our efforts to exert an influence over one another, in religion, in politics, in trade, in education, and in disease, we all feel that this nebulous something has to be taken into account.

It appears as the resultant of various forces in the individual, and gives distinction and point to the character, in short, individuality to the individual. It is shown in the bone, in the outline, the motion, the thought, and the temper. The name implies that it is the tempering and mixing of different characteristics or qualities together, rather would it seem to be the resultant produced from the convergence of several forces and tendencies in the individual.

The ancient writers upon our art endeavored to explain these different underlying forces as due to certain humours, the history and description of their views is too well known for me to recapit-

ulate them here. We moderns have accepted and must still accept much of their nomenclature, but we have rejected their explanations of the causes of the several temperaments, without seriously concerning ourselves with finding new ones. A recent writer in *The Medical Record* (August 4, 1888), in reviewing two essays of Hellurg, upon temperament, says, "Physicians learn, consciously or unconsciously, to recognize temperamental differences, and to suit both manner and medicine to the fact." He further goes on to remark that the best definition has been given by Muller, who essentially describes temperament as "The reaction of the individual to his environment." In the same article Hellurg's tabular definition of temperament is presented, which is founded on the view that it is the varying strength of the reception of an impression and of the reaction of the individual to it, that distinguishes the temperament.

HELLURG'S TABLE.

TEMPERAMENT.	RECEPTION.	REACTION.
Choleric.	Strong.	Strong.
Sanguineous.	Strong.	Feeble.
Melancholic.	Feeble.	Strong.
Lymphatic.	Feeble.	Feeble.

Darwin Hudson (Johnson's Encyclopædia) defines temperament "As a mixture or tempering of the essential elements of the body, whose excess or variable quantity determines the chief characteristics of mind or physique."

What are the essential elements of the body? In the various definitions of temperament that are to be found there is always a reference to some such undefined factors as being at the foundation of the problem of temperament. Before we can build up any reasonable scheme of temperament we must clear off the wrappings and expose the root of the matter, in short we must explain what is meant by the essential elements of the body.

What is the essential quality of living matter? its power of renewal, that is, nutrition. When a portion of elementary living matter, which we term protoplasm, becomes separate and individual, as in an amœba, what is the essential quality of its individuality? It is its capacity to receive an impression from and its power to react to its environment. This quality is exercised through nerve force. It is true that we cannot detect nerve structure, as we know it, in the dawning life of the individual, but though the localized and visible machinery, which we term nerve tissue, is not apparent, the real essential element of nerve force is undoubtedly diffused through the general mass of the individualized protoplasm, conferring on it the capacity to receive impressions, at least in an elementary manner.

The first reaction of the separate piece of protoplasm to the reception of an impression received from its environment would appear to be the formation of a cell wall, whereby it reacts to external

pressure by hardening itself superficially. Thus it defines its individuality and protects itself in the exercise of its essential function of nutrition, which function consists of the importing of raw material for food and the manufacture of it into the structure of the individual. The first evidences of a nervous system show that it is used to receive and react to impressions made from without; the passing food is drawn in when reflex action is developed by the impression received from without.

Thus we see that a living individual has two essential qualities, nutrition, whereby it lives, and innervation, whereby it individualizes itself, both essential to each other.

The evolution of nutrition is, briefly, thus: Simple absorption and assimilation of food by the whole mass of protoplasm and the general excretion of its waste; then the localization of digestion in a stomach; next the carrying of the digested nutriment to remote parts by lymphatic vessels, then this circulatory process elaborated into a vascular system, with its heart or pump. Then a portion of the clear, white lymph gradually changed into red blood, then the chemical changes producing bodily heat. Thus the circulatory system of nutrition passes from a lymphatic, cold-blooded stage to the warm, red-blooded form of the mammal.

The nervous system beginning in the sympathetic form, next the motor and sensory, up to its highest elaboration in the brain of man, with its power of receiving impressions without bodily contact, by means of thought.

Through innervation comes the power of reception of impressions made upon the individual.

Through nutrition the power of reacting to such impressions, the latter being exhibited immediately through its circulatory system, which in man in its most important form, with respect to the power of reaction, is sanguineous.

The essential difference in reception is in speed, and, therefore, the two chief divisions are into quick and slow. Quick reception may be best called "nervous;" slow, "phlegmatic."

The essential difference in reaction is in strength, therefore the chief division is into strong and weak. Strong reaction may be called "sanguineous;" weak, "lymphatic."

Thus temperaments should be primarily divided into those of quick reception, nervous, and those of slow, phlegmatic, those of strong reaction, sanguineous, and those of weak, lymphatic. But as each individual has both qualities of reception and reaction, so each quality should be expressed in the name of each temperament; therefore taking these four in their main varieties of combination, we have eight different temperaments, the first of the names signifying the most pronounced of the two qualities as exhibited in the temperament.

TEMPERAMENT.	RECEPTION.	REACTION.
1. Nervo-sanguineous.	Quick.	Strong.
2. Nervo-lymphatic.	Quick.	Weak.
3. Phlegmo-sanguineous.	Slow.	Strong.
4. Phlegmo-lymphatic.	Slow.	Weak.
5. Sanguineo-nervous.	Quick.	Strong.
6. Sanguineo-phlegmatic.	Slow.	Strong.
7. Lympho-nervous.	Quick.	Weak.
8. Lympho-phlegmatic.	Weak.	Weak.

No mention has been made of a normal or balanced temperament, as it was styled by Galen, it being an ideal not met with in real life. The nervo-sanguineous, or perhaps rather the sanguineo-nervous, would be nearer to it, that is with respect to quality, though it may not be in regard to quantity. That is, it is normal when the reception of an impression is in proper degree to the cause. For instance, a normally nervous person, when angered with sufficient cause, would not let his passion run riot, but would fit it to the occasion, while the abnormally nervous person is thrown into a passion by a trifle or is over-excited by trifles. The normally sanguineous individual, when affected by disease or injury, responds by vascular excitement and perhaps even inflammation, sufficient to defend his tissue or repair the damage, and no more. The phlegmatic temperament is always behindhand in its work of reception, and is evidently a type of arrested evolution at the stage when the sympathetic and motor systems are well developed and the sensory yet incomplete.

The lymphatic temperament always lags behind in reacting to the stimulus conveyed to it through the nervous system, and may be looked upon as a type of arrested evolution at a stage when the change from white, clear, cold lymph to red, thick, hot blood is going on, but is not fully accomplished.

An individual born with a certain temperament can undoubtedly modify it considerably by force of will and education. Circumstance or disease will also modify, and permanently or temporarily change the relative force of its phenomena. Change of climate often exaggerates or diminishes certain of its manifestations. As physicians the impression made upon temperament by disease is what chiefly concerns us. The reception of the impression made by the invasion of the body by disease is quick or slow, excited or calm, according to whether the individual is of the nervous or phlegmatic, and reaction is strong or weak as he is of the sanguineous or lymphatic temperament. Thus, in the nervo-sanguineous person affected by disease the tendency is to exaggerated nervous excitement and inflammatory change. In fact, the call to arms is quick and loud, and the defense of the citadel of life is vigorous, the rapid circulation promptly expelling the offender by excretion, or, if a lodgment has been gained, building up earthworks of plastic exudation and limiting the mischief; but, like vaulting ambition, nature oft

o'erleaps herself and falls on the other side. Thus the physician may have to moderate the excitement of both nervous and vascular systems, and later, perhaps, to treat the products of over-zealous inflammation. In the nervo-lymphatic, the same excitement of the nervous system is seen, but the excretion of the *materies morbi* is too feebly executed and the defensive lymph changes are too slight to protect, so the disease spreads through the system with much irritation and but little inflammation; the temperature being often higher than the amount of the inflammation appears to warrant.

In the phlegmo-sanguineous individual, on the other hand, the inflammation, which tends to be great, is out of proportion to the rise of temperature and nervous irritation, which are comparatively slight.

In the phlegmo-lymphatic both inflammation and temperature, vascular excitement and nervous irritation, are slight, and fail to reveal the amount of damage done by disease, the progress of which, when once begun, is uninterrupted by the defenses thrown out by inflammation. Knowing the temperamental type of a patient, we can explain and allow for many of the incongruities of pulse, temperature, and nervous phenomena that we meet with.

How are we to diagnose the temperament? Is the individual plethoric or anæmic in appearance? finely chiseled in feature and small-boned, or coarse in outline and large-boned? is he mentally quick or slow in conversation, and nervous or phlegmatic under our examination? is his view of his case exaggerated in its despondency or cheerfulness? Does his history show a tendency to inflammation or to passive congestion? Is he inclined to fever? Does he react quickly to cold? Are his feet usually warm? These, suggestively, are some of the observations and questions which will give us the material for classifying a patient's temperament.

The old classification of temperaments into hot and cold suggests the sanguineous or hot and full-blooded, the lymphatic the cold and thin-blooded. The old forms of dry and moist are suggestive of the nervous and phlegmatic, high nerve tension and dryness being necessarily allied, while moisture and low tension are equally inseparable.

If Hellurg's table and the one herewith presented are compared, the first four temperaments are identical except in name. The nomenclature suggested is somewhat cumbersome, and if it could be lightened without losing the advantage of the name conveying the meaning and the dual nature of the temperament, it would doubtless be better. The chief advantage, if the previous premises are accepted, is that the meaning and the name are linked together, instead of, as in other titles, the meaning being open to various

interpretations and merely suggestive of ancient physiological errors and not of the underlying and causative physical facts.

These definitions admit of subdivisions if needed to describe particular temperamental peculiarities, as in the nervous system when the mental, motor or sympathetic systems appear most prominent in excess or deficiency of action; or with respect to special phenomena of nutrition as exhibited in the working of a special organ, as the liver, stomach, etc. All these, however, will be found to ultimately range themselves under the divisions here given. Diatheses which are pathological temperaments, and excess or deficiencies of function dependent upon pathological changes, are not here considered.

In presenting this plea for placing the rational consideration of temperament among the scientific means at our command for forming a diagnosis and conducting a treatment, I desire to do something towards a revival of the study of the physiognomy of the diseased person. In the proud possession of our arms of precision and our more scientific knowledge of disease, we modern Æsculapians have too much neglected what might be deemed the observing of the *tout ensemble* of our cases; a valuable aid to diagnosis which, from their very poverty of resources, our parent leeches cultivated with success, whilst we, through our comparative richness of weapons, have too much neglected.

Therefore let us be ambidextrous, and while in one hand we bear to suffering humanity the fruits of our knowledge of disease, in the other let us carry those gathered from our study of the individual.

EXTRA-UTERINE PREGNANCY. OPERATION. RECOVERY.

Read at the Regular Meeting of the Philadelphia County Medical Society, April 19, 1889.

BY E. P. BERNARDY, M.D.,
OF PHILADELPHIA.

On the morning of November 15, 1888, I was requested to see Mrs. F., who had been taken suddenly with a sharp agonizing pain in the abdomen; the pain came on while in the yard, and it was with the greatest difficulty she was brought to her room. I saw her very shortly after, and found her suffering from shock: pulseless, upper and lower extremities cold, face pinched, complaining of pain in the left side of the pelvis; hot bottles were placed at her sides and feet; $\frac{1}{4}$ grain of morphine sulphate every fifteen minutes until relieved of pain; same evening pains somewhat easier, but have now assumed a colicky nature; found the menses had been arrested since September 13, 1888. Suspected intra-uterine pregnancy.

November 16. No sleep during the night, col-

icky pains all night, has recovered from the shock. Obtained the following history: Age 34 years. Married twice; four children by the first husband, none by the second; there seems to be a somewhat obscure history of gonorrhœal infection by the first husband; has been married eleven years to the second husband; has never missed her menses until at the time above stated.

The day previous to falling sick she carried up to the third-story room two buckets of coal; went to bed not feeling well; was taken, as stated above, with a sensation of something tearing in the abdomen, followed immediately by agonizing pelvic pain and collapse. Diagnosed ruptured tubal pregnancy.

17th. Vomiting the morphine; changed to rectal suppositories of ext. opii, gr. j. every two or three hours. Warm poultices over abdomen. Vaginal examination revealed a large and sensitive tumor on the left side and back of the uterus, so painful that the most careful examination elicited cries of pain.

From 18th to 25th all acute symptoms abated, the patient recovering her strength. On the 25th show of blood from the vagina, which continued for nearly two weeks; free from pain during the day, but at night is kept awake with colicky pains in the abdomen; pain extending down the left leg.

26th. Again made a careful examination; found a large, extremely sensitive tumor on the left side of uterus, somewhat to the back, throwing the uterus, which was enlarged, forward. Hinted the propriety of a consultation.

December 10. A large mass passed from the vagina, which was attended with expulsive pains, leaving the patient to suppose that she had aborted. It looked like the after-birth, was the remark of the patient. Unfortunately it was thrown away, as of no consequence, and I did not see it. The patient was hardly free of pain; walking or any sudden movement would bring on pain; loss of sleep.

23d. She called at my office, and after examination I informed the patient that her only chance was an operation, and desired further professional advice.

26th. Case examined by Dr. J. Price.

Operation December 29, 1888. Present: Professor Agnew, Drs. Levis, M. Price, Kynett, E. P. Bernardy. Operator, Dr. Joseph Price. The usual abdominal incision was made, and the abdominal cavity opened. Ruptured left tubal pregnancy. The left appendages filled the pelvic basin, the primary rupture having occurred between the folds of the broad ligament, with secondary rupture into the peritoneal cavity. General firm adhesions. The pelvis was emptied of clot, the placenta and membranes coming away in the tube, the right tube was diseased; hydrosalpinx; it was removed. Irrigation and glass

drainage. The patient is now entirely well; with the exception of a somewhat prolonged shock following the operation, there was no bad symptom.

The first natural question will be, Why was not the operation performed sooner? For two reasons: First, the patient rallied well from the first shock, there was relief of the acute pain and general improvement of health; the second reason, if I had suggested an operation at the first I would have undoubtedly been discharged. Feeling confident of my diagnosis, I made it my duty to gradually educate my patient up to the point of operation. When it was decided to operate I simply notified the patient she would be operated on within the next twenty-four hours.

The history was a typical one of an extra-uterine; hardly a symptom, as laid down in Parry's book on "Extra-uterine Pregnancy," was lacking, and any mistake in the diagnosis could only have been made through gross negligence.

DR. J. M. BALDY: A great deal has been said in regard to the influence of gonorrhœa in the causation of various affections. I notice that Dr. Bernardy has made it a prominent feature in his case; I would ask if he insinuated that the extra-uterine pregnancy was due to the attack of gonorrhœa?

DR. E. P. BERNARDY: I mentioned gonorrhœa simply as one feature in the history of the case. From the extensive disease in the opposite tube, I think there is reason to believe that the attack of gonorrhœa was at the bottom of the extra-uterine pregnancy.

DR. G. G. DAVIS: The question of the ligature coming away is one that is applicable to general surgery as well as to special abdominal work. There seems to be a tendency to attribute the trouble to the large size of the ligature. That a large knot or a large thread would give trouble where a small one would not is no doubt true, but I do not think it proper to attribute all the bad results to the size of the thread. Where pus follows the application of a large thread, it does not necessarily follow that the thread is the cause of the pus. It is well known that it is extremely difficult to cause pus by placing foreign bodies in healthy structures. If the bodies are infected it can be readily done. In the case referred to by Dr. Price the question might arise whether or not the trouble with the large ligature was due to its being infected, while the small ligature was not. Many years ago I saw Mr. Thomas Smith, in St. Bartholomew's Hospital, use silk to tie arteries. Some would suppurate and others would not. This was in the time of carbolic acid. There can be no question that the more correct are the anti-septic precautions, the greater the proportion of cases in which the silk ligature, whether large or small, will remain harmless and be covered with lymph.

DR. JOSEPH HOFFMAN: In my case of extra-uterine pregnancy I simply found a mass in the pelvis and recognized the importance of its removal. The history agrees closely with that given by Dr. Bernardy, although there was no history of gonorrhœa and no long preceding period of sterility. The case was a terrible one. I never saw such a mass of matted abdominal contents. The tube of the opposite side was so adherent to the intestine that in its separation the bowel broke. The gut was resected and dropped. The patient made an uninterrupted recovery.

DIGITAL DIVULSION OF THE PYLORUS FOR CICATRICIAL STENOSIS.

Read before the American Surgical Association, May 15, 1889.

BY J. M. BARTON, M.D.,
OF PHILADELPHIA.

Digital divulsion of the pylorus for cicatricial stenosis as first practiced by Prof. Loreta, of Bologna, Italy, in 1882, has scarcely received the attention which I think it deserves anywhere except in Italy. The mortality from the twenty-five operations which I have succeeded in collecting is not great, when we consider that every successful case is a patient rescued from certain and by no means distant death, and this mortality is already decreasing.

The cases in which the operation would be of service are not so rare. When searching the journals for records of such operations, I found the reports of the presentation of many specimens of cicatricial stenosis of the pylorus to various pathological societies. My own experience has been limited to two operations. Even the first, though it proved fatal on the fourth day, encouraged me to operate again, as I was fully satisfied that had it been performed earlier, when the patient was stronger, there was no reason why it should not have been successful.

My second case has the following history: Mrs. G., æt. 48 years, a patient of Dr. Adams, of Vineland, N. J., was first seen by me at her home near Vineland, in December, 1888. For convenience of study and operation, I admitted her to Jefferson College Hospital in January, 1889. During 1884, 1885 and 1886, she had suffered from gastric ulcer. She had pain and vomiting immediately after eating, the vomiting occurring as often as six times in the twenty-four hours; she lost greatly in weight and had two severe hæmorrhages. In 1887 all of the symptoms left her, and for the greater part of the year she enjoyed excellent health, weighing in January, 1888, 143 lbs., which was more than she had ever weighed in all her life. During 1888, she became very ill with symptoms of pyloric obstruction, and lost

flesh rapidly, weighing after her admission to the hospital (January, 1889) only 93½ lbs. She then vomited but once in twenty-four or forty-eight hours. This occurred when she laid down at night and was not accompanied by nausea. It was usually from 1½ to 2 quarts in quantity and measured nearly, and sometimes quite, as much as all the nourishment taken since the preceding act of vomiting twenty-four hours before. Many articles taken during the day could be recognized; indeed, she stated that she had occasionally been able to recognize articles eaten as long as two weeks before. As she took her meals she felt that the stomach was becoming more and more distended, and when she laid down at night, gravity brought the contents of her stomach into her throat and they were then vomited. Her bowels were obstinately constipated, acting only once in twelve or fourteen days, and then only after frequently repeated large injections; purgatives administered by the mouth producing no effect. She had lately been able to occasionally feel a small tumor, about the size of a hazel nut, 2 inches to the right of the umbilicus and situated quite deeply. Her stomach was greatly enlarged; distended by the carbonic acid gas developed from half of a soda powder, it reached as low as the umbilicus and as far as the small tumor, though we could not say that the tumor was connected with the stomach. The vomited matters separated themselves into the usual three layers, the middle one being quite clear. They were nearly free from undigested food and not offensive; free hydrochloric acid, though searched for, was not found.

The operation was performed in the presence of the class of Jefferson Medical College, February 16, 1889. The surface of the abdomen had been prepared the day before, the mercurial dressings being still on when the patient was brought into the amphitheatre. Her stomach had been washed out on the morning of operation with a solution of bichloride of soda. This had been repeated until the fluid returned quite clear. Chloroform was used as the anæsthetic in preference to ether, as being less apt to be followed by vomiting. The hands and instruments having been prepared with antiseptic solutions, I made a median incision through the skin about 4 inches long, terminating at the umbilicus. The peritoneal incision, however, was only 3 inches in length. There was but little bleeding, and it was readily controlled by clamp forceps.

The dilated stomach was found directly beneath the incision. The juncture of the stomach and duodenum, even from the outside, was markedly contracted and irregular on its surface. There were no adhesions and there was no tumor. The tumor was found to be a hard scybalous mass in the ascending colon, which also contained quite a number of smaller masses of hardened fæces. As the wall of the stomach, 3 inches from the pylo-

rus, felt quite healthy, I folded it transversely midway between the greater and lesser curvatures, and with a pair of sharp scissors made an incision between 1½ and 2 inches in length. There was no bleeding requiring attention. I introduced my index finger through the incision and felt the pylorus contracted to about the size of a No. 10 French catheter. Its margins were quite hard and fibrous. As the fingers would not enter, the blades of a small uterine dilator were guided by the finger into the contracted pylorus, which was then readily dilated until it admitted the index finger. With the aid of a pair of cesophageal forceps it was still further dilated until both the index and middle fingers were admitted, the two fingers were then separated about ½ inch, when I ceased, feeling that further effort would probably rupture the mucous membrane. This dilatation gave to the pylorus a circumference of 4½ inches.

The mucous membrane of the stomach at the point of incision was brought together by a continuous silk suture, and the serous coat by a continuous Lembert suture, also of fine silk carried in an ordinary sewing needle. This suture was introduced deeply into the muscular coat in order to obtain a firm hold; even then it tore out at one or two points, requiring an interrupted suture to be used at those places. When the finger was first introduced into the stomach it caused some retching, forcing most of the stomach out of the wound, where it was kept during the subsequent manipulations. After the wound in the stomach was closed the organ was carefully sponged and restored to the abdominal cavity. The abdominal wound was then closed and dressed in the usual manner.

The patient vomited about 4 ozs. of blood half an hour after the operation, but there has been no nausea and no vomiting since. She was nourished exclusively by the rectum until the fourth day. From that time until the fourteenth day she was fed upon peptonized milk and animal broths. After the seventh day she took from 48 to 60 ozs. of liquid nourishment in the twenty-four hours. Some solid food was given on the tenth day, and after the fourteenth day she was fed upon a carefully selected solid diet. On the thirtieth day after operation she was able to eat eggs, mutton chops, oysters, beef, chicken, lamb, potatoes, cream toast, bread and butter, milk and coffee. Her temperature has never been over 99° F. nor under 98° F. since the operation. Her bowels act naturally every day. The abdominal stitches were removed on the ninth day. On February 8, before the operation, she weighed 93½ lbs. March 25, she weighed 110 lbs., April 15, 118 lbs.; and April 27, 122 lbs. She was able to leave the hospital April 10. She had no pain at any time and required no anodynes.

I have succeeded in collecting 25 published op-

erations. Many of these are by Prof. Loreta. I had hoped to have obtained the results in all his cases, but Dr. Peruzzi, his chief assistant, replies to a letter of inquiry that the Professor has performed in all about 30 operations, and that at least 6 more have been performed by other Italian surgeons. They were all successful when the diagnosis was correct. This would make the total number of operations about 45. The 25 operations included in my list were performed on 24 patients, one patient having been operated on twice successfully by Prof. Loreta. From the 25 operations there were 15 recoveries and 10 deaths, making a mortality rate of 40 per cent. Of the 10 deaths, 6 were due to shock, 2 to hæmorrhage, 1 to tetanus and 1 to suppression of urine. The large mortality from shock in an abdominal section performed in from half an hour to an hour, is probably due to the fact that in this, as in most new surgical procedures, the operation is postponed too long. The mortality is already decreasing. Of the first 12 cases reported, 6 recovered and 6 died; while of the last twelve, 9 recovered and 3 died. This mortality can perhaps be still further lessened by earlier diagnosis and operation, and by such methods of operation as are most quickly performed and accompanied by the minimum loss of blood.

Diagnosis.—The diagnosis can be conveniently divided into two parts: 1, to determine the existence of pyloric obstruction, and 2, to differentiate between obstruction caused by cancer and that caused by cicatricial stenosis. But few of the reported cases has such a typical history as the one I have related. The co-existence of dyspeptic symptoms or of some still open ulcers complicated the diagnosis in most of the cases. I should regard as of little value some of the symptoms upon which much stress has been laid. The material vomited in some cases consisted of partly digested food, in some it was wholly undigested and offensive, while in others it consisted of well-elaborated chyme. The character of the material indicates the health and physiological activity of the stomach, but throws little light upon the condition of the pylorus. In some cases sarcinæ were present, but in many they were absent. The same may be said of starch granules, of needles of the fatty acids, of free hydrochloric acid, of pain and of other dyspeptic symptoms, which have usually existed for many years before the symptoms of obstruction occurred.

The following symptoms I would consider of value: 1. A greatly dilated stomach; 2. The vomiting of from one to two quarts of material at one time; 3. The recognition in the vomited matter of articles that have been taken many hours, days or weeks before; 4. When the act of vomiting is performed with great ease, without nausea, and the appetite is good immediately afterwards; 5. Obstinate constipation; 6. The non-effect

of ordinary purgatives; 7. A preceding history of gastric ulcer of several years' duration and temporary improvement followed by simple obstructive vomiting of well-elaborated chyme many

placed upon the detection of a decidedly enlarged stomach as this is rare, except as a result of mechanical obstruction of the pylorus.

The mere presence of tumor is almost without value in the differential diagnosis between cancer and stenosis. In the 24 cases tumor was present in 7, absent in 4, not noted in 13. A rapidly growing nodulated tumor low down in the abdomen is probably malignant. A poorly-defined tumor, not increasing in size, high in the abdominal cavity is probably non-malignant. The average duration of cancer of the pylorus is one year (Brinton); the maximum duration three years (Bartholow). The average duration of the gastric symptom in 13 of the 24 cases in which this is noted was eleven years. The history of temporary improvement is against malignant disease. In the latter stages of cancer the obstruction is often removed by ulceration and diarrhea occurs. In the later stages of ulcer the obstruction increases and the stenosis is more obstinate.

The Abdominal Incision.—In all of the reported cases but two methods of opening the abdomen have been used. One by an incision running from 1 inch below the ensiform cartilage to the extremity of the 9th rib on the right side, a distance of about 6 inches; the other by an incision in the median line between the ensiform cartilage and umbilicus, and from 3 to 6 inches in length. The first method was used by Loreta in his earlier cases, but he now uses the latter exclusively.

The stomach wound should be made far enough from the pylorus to be in healthy tissue. If some inches from the pylorus it will be outside the zone of inflammation following the dilatation. Experimenting upon cadavers I found that separation of my fingers more than an inch caused rupture of the mucous membrane.

The stomach wound has been closed in many ways and all did well. In no case was there the slightest leakage. No case suffered from peritonitis and in none was the stomach wound the cause of death. I would suggest that probably the best method would be a continuous suture of catgut to the mucous membrane and the suture of Appollito to the peritoneum.

Diet.—In some of the reported cases food has been given as early as a few hours after the operation, without injury. I delayed until the fourth day, although I see no reason why food should not be given earlier. Peptonized milk, animal broths, diluted wines, and the yolks of eggs would be the best articles, according to the condition of the stomach prior to operation. Rectal alimentation will be required until sufficient food can be given by the mouth. Solid food has rarely been given before the tenth day and then sparingly.

Permanency of Cure.—Recontraction of the cicatricial tissue would naturally be feared, but Loreta, in January, 1885, nearly three years after his first

Letter to Dr. Harris stating that to Nov. 30, 1888, he had had 4 cases, of which 5 were cured and 1 died, 3 from shock and 1 from hemorrhage

hours after taking food. This typical history occurred but twice among the 24 cases. When the symptoms are obscure great reliance may be

operation, writes, "I have now operated on 6 cases. They all have recovered, and all remain well up to the present time." Haggard, in 1888, reports that the case he operated on two years before was "still perfectly well, no vomiting, dilatation of stomach less, and she has recently married." Peruzzi, in his letter to me, March 22, 1889, states that he knows of only one relapse among the 30 cases upon which Prof. Loreta has operated. This patient was re-operated upon, recovered, and remained well.

In one of the fatal cases included in the list the obstruction was valvular, due to irregular contraction of the walls of the stomach. In another case, not included in the list as the stomach was not opened, the valvular obstruction was caused by distortion produced by external adhesions. These were divided and the patient made a good recovery. In another case, not included in the list, the operator recognizing that he had badly ruptured the mucous membrane while stretching the pylorus, immediately performed pylorotomy, with recovery of the patient. In another case the obstruction was caused by an adherent pancreas. The cause of the adhesion was an ulcer starting in the posterior wall of the stomach and penetrating the pancreas. In this case an incision about 2 inches in length was made from stomach to duodenum, passing through the pylorus. The two extremities of the wound were brought in contact and the wound sewed up at right angles to its position when made. When completed it was parallel to the long axis of the body. This patient recovered after a serious illness.

AN INTRODUCTION TO THE STUDY OF PNEUMONIC FEVER.

BY EDWARD F. WELLS, M.D.

SIXTH PAPER.

PREVALENCE—METEOROLOGY.

The relations existing between meteorological conditions and pneumonic fever are of the most interesting nature, and many and various are the rules and laws relating thereto that have been formulated by systematic writers, but the exceptions to them are so numerous and important that they are greatly weakened or rendered entirely nugatory.

It may be affirmed, as a general proposition,¹ that pneumonic fever will be found to prevail to a greater extent than ordinarily, the influence of season and epidemics excepted, when the daily range of temperature,² humidity of the atmos-

phere,³ velocity of the wind,⁴ range of barometer,⁵ amount of atmospheric pressure⁶ and amount of ozone⁷ present in the air are greater than the average, and that it will be less prevalent when opposite conditions prevail. Again, it will be found that an excess of cases will be met with when the range of temperature is low,⁸ the barometer falling⁹ and the ground water low.¹⁰

That a sudden and marked fall of the thermometer is apt to be followed by an excessive prevalence of pneumonic fever has always been recognized, but it is not at all clear how an excess of moisture can have, *per se*, any deleterious effects upon the lungs, and the proposition has been controverted by a large number of observers.¹¹ If, however, as is claimed by many, the air which, *par excellence*, is connected with the prevalences of pneumonic fever is a dry, cold one, the explanation offered by Baker¹² is at least plausible:

"If, as is believed, the air is exhaled from the lungs at nearly a uniform temperature throughout the year, and is saturated, or nearly saturated, with the vapor of water, the cold air of winter must, because of the small quantity of vapor which it contains, take from the lungs and air-passages a much greater quantity of vapor than does the warm, moist air of summer; and thus its drying and irritating effects must be much greater."

In this connection it must be remembered that during the season when pneumonic fever is rife a very large proportion of the population is cooped up in heated rooms and habitually breathe a dessicating atmosphere surcharged with carbonic acid gas.

In every locality certain winds are more likely to be followed by pneumonic fever than others. Those from the North are particularly injurious in New York,¹³ Stockholm¹⁴, on the Spanish and Ital-

ian¹⁵ coast, Quito,¹⁶ England,¹⁷ Cayenne,¹⁸ and other places. North-west winds are the most deleterious in the Interior Valley of North America,¹⁹ Germany,²⁰ Marseilles,²¹ etc., and the East wind in the Levant.²²

Seibert,²³ in analyzing 600 cases, found that the barometer was falling in 461 and rising in 139. It was below the mean in 352. The temperature was below 50° F. in 506. The wind was northerly in 302 and north-westerly in 200, and the velocity more than 15 miles per hour in 406. In 550 the air was cold and moist.

There can be no doubt as to the important rôle played by meteorology in preparing either the soil²⁴ or the seed—or both—of pneumonic fever, but after examining an immense amount of facts relating to this point I am compelled to confess, with Sturges,²⁵ that I have been unable to come to any satisfactory conclusions.²⁶

CLIMATE.

Climate has always been regarded as being intimately associated with the prevalence of pneumonic fever, although the facts at our disposal do not enable us to indicate with certainty the varieties of climate which are most or least prone to influence the prevalence of the disease.

Upon this subject writers have entertained many and diverse views: Laennec was of the opinion that, in general, pneumonic fever is a disease of cold climates, and this view has been shared by others.²⁷ Saunders²⁸ considers it most frequent in warm countries, whilst others maintain that it can not be shown that the disease is absolutely more prevalent in one climate than another.³⁰

Although pneumonic fever prevails very extensively upon raw and unprotected coasts and in localities³² which suffer from marked atmospheric vicissitudes, yet it does not appear that the rigorous climate of polar regions is accompanied by as great a prevalence as milder parts. Thus in Parry's northern expedition the men were sometimes exposed—in emerging from their quarters—to a

sudden change of temperature of from 80° to 120° F., yet no cases of the disease occurred.³¹ It is possible that a prolonged sojourn in Arctic regions may predispose to this and other pulmonary disorders upon a return to temperate climates.³³

Ever since Forry³⁴ first promulgated his theory "that in proportion as the high temperature of summer makes an impression upon the system do the lungs become susceptible to the morbid agency of the opposite season" and attempted to prove that this disease prevails most extensively in warm climates, this view has had many adherents.³⁵ Examining the facts adduced by Forry, Sanders³⁶ and others in support of the proposition it must be conceded that they are forcible and appropriate, yet when we cast our eyes over a more extensive field the puzzle becomes more complex—perhaps insoluble.³⁷ When we see localities having similar climates with widely divergent rates of prevalence, or several places with the same rates presenting opposite climatic conditions, it is evident that climate alone is not the ruling factor in the distribution of pneumonic fever.³⁸

SEASON.

It is the custom of writers³⁹ to say that in the northern hemisphere, pneumonic fever prevails very much more extensively in winter and spring than during the summer and autumn months, and this seems to be the only legitimate conclusion if we consult only mortality reports, but if we look at clinical reports as well we may hesitate to accept this dictum. The facts are clearly shown in the following tables.⁴⁰

During a series of 24 years there were treated in the Vienna General Hospital 12,104 cases of pneumonic fever, and of these 64 per cent. were admitted during the six cold, and 36 per cent. in the six warm months. Of 395 cases admitted into

³¹ In California the disease is noticed oftenest upon the sea-coast and the mountains, where the air is cold and moist, whilst it is extremely infrequent in the warmer interior valleys where extreme vicissitudes of temperature are rare. Tyrrell, Rpt. St. Bd. Health, 1886, p. 65.

the Hôtel Dieu from 1831-39, 227 occurred in winter, and 168 in summer. Epidemics have generally occurred in winter and spring.

The inference to be drawn from these statistics is that pneumonic fever is markedly more fatal in winter and spring than during the warmer months, but the material at hand is too meager to statistically settle the point.⁵⁹

⁶⁰ See Hermann, op. cit.

The influence of season over the prevalence of the disease varies considerably in different years and localities,⁶⁰ due no doubt to local and temporary influence. Race, sex, age, etc., influence slightly, if at all, the seasonal prevalences of pneumonic fever. The influence of age is shown in table xv.

At certain periods pneumonic fever forms a greater portion of the total morbidity than at others as shown in table xvi.

VAGINAL HYSTERECTOMY FOR CANCER.

A CONTRIBUTION TO THE STATISTICS OF THE OPERATION.

BY DOCENT DR. VACLAV RUBESKA,

OF PRAG.

[Translated by ARCHIBALD CHURCH, M.D.]

The justifiability of the above operation is even yet at times the subject of debate, but if the consensus of opinion is to the effect that complete, early removal of cancer in other localities gives the patient the best, if not the only chance for recovery, application of the same conclusion to the uterine variety seems to furnish a sound foundation for hysterectomy. The remarkable experience of Dr. Rubeska in the gynecological clinic of the Bohemian University at Prag, now for the first time published, adds much strength to this

position. Brief notes of all his cases, extending over four years, were placed in the writer's hands. Twenty-seven cases of vaginal hysterectomy for cancer without a death from the operation speaks in no uncertain terms and needs no comment.

No peculiar mode of operation was employed excepting that the stumps of the broad ligaments were drawn well into the vagina and stitched to its walls. The reason for this procedure, upon which Dr. Rubeska strongly insists, is that a recurrence of the neoplasm, by extension or otherwise, naturally occurring in these structures, will be, when this step is taken, within the range of observation and the field of subsequent operative treatment. Ovaries and tubes were not removed unless diseased. In the first three cases iodoform gauze was used for drainage, but later the peritoneum was closed and no drainage whatever employed. In other respects the operation did not differ materially from the Czerny-Schreder method, though usually the uterus was delivered without being inverted. The cases were not selected in any sense of the word, and in one case a radical operation was impossible owing to the extensive infiltration of the surrounding structures. Almost without exception the patients were of the poorest class, making it often impossible to keep in view the subsequent course of events. Antiseptic precautions were carried out in their detail, but the

VAGINAL HYSTERECTOMY FOR CANCER

Case No.	NAME.	Age.	Location of Growth	Date of Operation	COURSE MORE	Condition of Patient July 1, 1888.
1	Teressa V.	48	C. corporis uteri.	Sept. 25, 1884.	Quickly recovered from operation.	Is still well.
2	Marie S.	35	C. cervicis uteri.	Nov. 2, 1885.	Recurrence of disease in three months, and death six months after operation.	
3	Teressa H.	36	C. cervicis uteri.	Nov. 6, 1885.	Was discharged well and lost sight of.	Unknown.
4	Barbara N.	42	C. corporis uteri.	Nov. 17, 1885.	Discharged well and lost sight of.	Unknown.
5	Teressa M.	43	C. cervicis uteri.	Nov. 30, 1885.	Discharged well and lost sight of.	Unknown.
6	Anna A.	41	C. portionis vaginalis.	April 2, 1886.	Discharged well, but died from recurrence of disease in the vaginal wall at a distance from the cicatrix, which remained intact.	
7	Madalane K.	38		April 9, 1886.	Discharged well and lost sight of.	Unknown.
8	Eleuora H.	63	C. corporis uteri.	May 18, 1886.	Discharged well; died six months later of pneumonia, without recurrence.	
9	Anna F.	47	C. cervicis uteri.	June 6, 1886.	Discharged well and lost sight of.	Unknown.
10	Barbara S.	53	C. corporis uteri.	Aug. 9, 1886.	Discharged well.	Remains well.
11	Alvira N.	54	C. cervicis uteri.	Aug. 18, 1886.	A small urethro-vaginal fistula resulted, but closed spontaneously.	Remains well.
12	Frances S.	48		Aug. 26, 1886.	Discharged well.	Unknown.
13	Rosalie T.	34	C. port vaginalis.	Nov. 28, 1886.	Discharged well.	Remains well.
14	Katerina K.	34	C. cervicis uteri.	Dec. 18, 1886.	Discharged well.	Unknown.
15	Amanda R.	52		Jan. 31, 1887.	Discharged well. Died of empyema April 28, 1887. Post-mortem the cicatrix was entirely free from carcinoma.	
16	Teressa K.	41	C. port vaginalis.	March 30, 1887.	Discharged well.	Unknown.
17	Anna P.	38		May 28, 1887.	Discharged well.	Unknown.
18	Anna B.	53		June 4, 1887.	Discharged well.	Unknown.
19	C. R.	34		June 26, 1887.	Discharged well. Operated in small country house.	Remains well.
20	Anna S.	41		July 2, 1887.	Discharged well.	Recurrence of growth.
21	Marie M.	58		July 3, 1887.	Thrombosis of crural and uterine veins. Died from recurrence of growth April 21, 1888.	
22	Marie L.	50		July 20, 1887.	Discharged well.	Remains well.
23	Frances B.	48		Aug. 16, 1887.	Operation not radical as parametrium was widely infiltrated. Left urethro-vaginal fistula.	Recurrence of growth.
24	Teressa F.	56	C. corporis uteri.	Aug. 18, 1887.	Discharged well.	Remains well.
25	Marie Z.	60	C. port vaginalis.	Aug. 28, 1887.	Discharged well.	Remains well.
26	Marie C.	59	C. cervicis uteri.	Feb. 23, 1888.	Hæmaturia after operation. Discharged well.	Remains well.
27	Katerina K.	42		April 25, 1888.	Discharged well.	Remains well.

clinic being in a portion of the general hospital, an old building leaving much to be desired from a hygienic point of view, the circumstances were

not the most favorable, and one operation was done in a small country house.

Whenever doubt existed as to the diagnosis, and as a rule, microscopical examination of the growth was made.

Of the seventeen cases treated to July 1, 1888, ten remained well after periods of 46, 23, 23, 18, 13, 12, 11, 11, 4, and 3 months respectively. Three died with recurrent cancer; two presented a recede on that date; and two had died from other diseases without any recurrence of the growth whatever. (For tabulated list see p. 805.)

3300 Cottage Grove Ave., Chicago.

MEDICAL PROGRESS.

VERTIGO OF THE STOMACH CONSIDERED OF TOXIC ORIGIN.—M. BOVET has made two kinds of investigations. First, an examination of the urine of dyspeptics affected with vertigo. Second, an analysis of the gas of the belchings so frequent at a certain stage of digestion with patients afflicted with vertigo. It is necessary to fix precisely the moment when the gaseous products are collected, for their nature differs essentially according as they form a short time after eating or from five to six hours afterwards. If the first is the case nitrogen and carbonic acid are the chief ingredients; if the latter hydrogen sulphide often is added, and sometimes an ingredient of a sulphocyanic nature, which Bovet found again as sulphocyanic acid in the urine; he thinks that this toxic product acts upon the medulla and determines the phenomenon of vertigo. Poisoning with the derivatives of cyanide produces vertigo and tingling of the ears, symptoms which are often found in dyspeptic patients. There is, consequently, good reason to believe that these organic poisons which were discovered in excess fourteen times out of the seventeen analyses of urine which Bovet made, and five times in those of the stomach gases, constitute the cause of vertigo.

Does this mean that the cyanide compound, which in its nature would be ethylaceto cyanhydric acid, a substance originating from the reduction by dehydration of ethyldiacetic acid and from the derivatives of cyanide in the urine is alone to blame? Bovet does not think so, as other substances equally poisonous were found in the urine, such as oxybutyric acid B, which originates from acetic acid, crotonic acid, diacetic acid, ethylacetic acid, and acetone, and which was discovered in certain conditions of diabetes by Külz and Minkowsky. Lépine (Lyon) even ascribes to it the coma in diabetes. It is, therefore, possible that vertigo of the stomach is due to the presence in the organism of one of these two acids, or perhaps to the presence of some other acid of the

same kind, for through Gehhardt's reaction the same red coloring is obtained for all these substances derived from one another. As to the sulphocyanic acids and the ethylaceto cyanhydric acid in the urine of vertigo patients Bovet was able to prove after distillation the mixed reaction of these two substances which, moreover, had a distinct smell of prussic acid. Although making certain reserves regarding the nature proper of the acid found in the urines, or in the alkaline solution in which Bovet collected the gases from the stomach, he thinks that this acid acts by intoxication. For inasmuch as it belongs to the hydrocyanic or butyric series, its toxic power is the same and, consequently, its effects are identical. More investigations will be necessary to elucidate this point.—*La Semaine Médicale*, No. 18, 1889.

CONTAGIOUS CHARACTER AND TRANFERABILITY OF CANCER BY INOCULATION.—DR. ARNAUDET has published the statistics of a district in La Normandie afflicted with cancer, from which he draws the following conclusions:

1. Cancer prevailed with excessive intensity in this part of La Normandie; there exists consequently a local cause.

2. Clinical results justify the declaration that carcinoma is infectious and may be transmitted from one individual to another.

3. As in typhoid fever, so in cancer, the water is ordinarily the vehicle of the characteristic microbe, in our district probably the cider.

4. All water coming from pools, and all impure water in general should be excluded from the fabrication of cider.

5. Our knowledge of this disease makes it our duty to destroy as far as possible all morbid products of our sick (vomited matter of cancer patients, sputa of patients with phthisis, stools of typhoid patients, etc.) Where a more powerful antiseptic is lacking, boiling water is always obtainable.

Arnaudet makes these observations: The specific microbe has not yet been found, and experiments on animals have not led to any positive results. Experiments on man can neither be excused nor advised, but it is well to remember the case of the famous dermatologist Alibert, an opponent of contagion, who died from cancer after having inoculated himself with the juice of an encephaloid, thus proving the very theory which he wished to disprove.

It seems proven that physicians and surgeons pay a greater tribute than the rest of mankind to this terrible malady with which they have to struggle so often. English journals have reported several observations of direct contagion: a cancer of the penis in a man whose wife had a uterine tumor; specific ulceration of the hand and tumor of the arm-pit in a woman who took care of her mistress, the latter being affected with carcinoma

of the breast, the woman had also been washing the linen of her mistress, etc.

Assuredly more material will be necessary to establish all these ideas beyond a doubt, but already the day may be looked forward to—perhaps it is not distant—when like tuberculosis, cancer will fall from the rank of diatheses to that of a simple local disease with external causes.—*L'Union Médicale*, No. 52, 1889.

ON SURGICAL INTERVENTION IN TUBERCULAR PERITONITIS.—It has often happened and still happens that after diagnosing an abdominal tumor the abdomen is opened and tubercular peritonitis encountered. However, surgical intervention is sometimes useful in such a case, despite the mistaken diagnosis. M. CECHERELLI, of Parma, has tried to ascertain, 1, which are the cases of tubercular peritonitis in which surgical intervention is beneficent; 2, what are the reasons of the usefulness of such intervention. Four patients in his clinic gave him opportunity to study these questions. In two of them, a woman 32 years old, and a boy 11 years of age, who presented an enormous tumefaction of the abdomen, with fever, pains, etc., laparotomy, with extraction of several litres of liquid, followed by rinsing and dressing with iodoform, produced a complete cure. In one of these cases, the second, a relapse after three months enabled him to establish, *de visu*, the process of cure. He had to perform another laparotomy, which showed the existence of a large number of loops and adhesions between the parietal and visceral peritoneum. The third and fourth patients were children, in whom the ascites was inconsiderable and encysted in pockets, which he could open, drain, rinse and clean. All patients recovered, and in all the diagnosis of tubercular peritonitis was confirmed by the examination of the peritoneal fragments and of the liquids which were extracted. He thinks from his experience that laparotomy in peritoneal tuberculosis is especially useful in cases where there is considerable dropsy, the cure following, in Cecherelli's opinion, by the intermediation of an adhesive peritonitis after the laparotomy, with binding new formations which enclose and stifle the tubercles. In cases where these adhesions exist already it is not necessary to produce them by surgical intervention.—*La Semaine Médicale*, No. 17, 1889.

ON THE INFLUENCE OF TOBACCO SMOKE ON DIPHThERIA.—This question has been discussed in the medical college in Vienna. Supported by the discovery of Tassinari, of Pisa, which proved that the fumes of tobacco obstruct the development of the microbes, Dr. Hayack studied the statistics of the city of Vienna, to see whether cases of diphtheria were less numerous in men, generally smokers, than in women. In the last four years, 1885–1888, the proportion of cases in

men and women was 1:2.8; these figures confirmed, therefore, the results obtained by Tassinari. Dr. Unterholzer does not think that tobacco smoke has any influence on the progress of diphtheria for, according to statistics, the mortality of this disease is 4 per cent. less in women than in men. Dr. Neudörfer accounts for the antibacteric action of tobacco smoke by the presence of pyridine, which is a bactericide. It may be remembered here that in bacteriological laboratories smoking is forbidden, as the smoke impedes the development of the cultures. A conclusive experiment of this kind was made by Israël in Virchow's laboratory.—*L'Union Médicale*, No. 54, 1889.

ANTISEPTIC POWER OF SALOL.—At a recent meeting of the Hunterian Society, MR. CORNER introduced a series of cases illustrative of the antiseptic power of salol (salicylate of phenol) as a dressing for wounds, after the part had been rendered aseptic by a 1 in 20 solution of carbolic acid. He did not claim for it greater power than iodoform, and probably other antiseptics, but it has advantages over some. It possesses a pleasant aromatic odor, can be used freely without fear of irritation or poisoning, is absorbent of moisture, which drying forms a hard but friable covering. It will prevent putrefaction; it will not destroy it when once established. It has been used in increasing frequency for several years at the Poplar Hospital, and with excellent results, in compound fractures and dislocations, also as a dressing in amputations, minor and major, and in compound comminuted and depressed fractures of the skull. The first case shown was a compound comminuted depressed fracture of the frontal bone, in which the bone was elevated and some spicules removed. Afterwards the wound was washed with a solution of carbolic acid (1 in 20), the opening filled with salol, and a drainage-tube inserted. The dressing was undisturbed for fourteen days, remained sweet, and healed on the twenty-sixth day. His temperature remained from the first under 100°. A second case treated in January, 1889, was a compound fracture of the olecranon, head of radius, and humerus, opening the elbow joint, with considerable damage to soft parts, the elbow having been crushed by the passage of a railway engine over it. The olecranon was splintered and drawn up, causing serious tension of skin and necessitating removal of both portions. The antiseptic treatment and dressing were the same as in the previous case, but required changing after four hours and again next day, in consequence of oozing through. The parts were then left untouched for thirty days. The temperature went up the day after the injury, and remained about 101° for three days, 100° for two days, and then fell to normal. Two other cases were shown: one a crushed compound fractured finger,

dressed twenty-one days before, and not exposed since, there having been neither pain nor elevation of temperature; the other was a compound fracture of first phalanx of finger, only dressed at the time of the accident, and left undisturbed for a month, when it was found perfectly healed. It was pointed out that this was the common experience in such cases, and that even if gangrene followed the parts remained sweet.—*Lancet*, May 4, 1889.

CASE OF HYSTERIA MINOR AND OVARIAN PHENOMENA IN A MALE.—DR. SAVILL, of the Paddington Infirmary reports the following case in *The Lancet* of May 11. C. G., æt. 20, who had been a shoeblick and paper-seller, was admitted into the infirmary on Dec. 7, 1888, for granular lids and irregular action of the heart. The heart appeared normal, and there was (?) no valvular lesion. He was pale and anæmic, but presented no feminine qualities, and the organs of generation were well developed. On April 5, when he was being prepared for an application of the mitigated nitrate of silver stick, he was taken with a nervous attack. He complained of a ball rising in his throat, and a stifling feeling and pain in his chest. Then he gasped for breath, the limbs became rigid, he assumed the position of opisthotonos, and slid off the chair on which he had been seated. There were no clonic convulsions, but the sighing respiration, rigidity, and other symptoms lasted for several minutes, when, water being thrown in his face, he recovered.

On search being made for other hysterical symptoms no alteration of sensation could be discovered, but there was very marked tenderness in both inguinal regions. The lightest pressure in either groin was resisted by the patient, and produced a recurrence of the above-described "attack" in a much more accentuated degree, accompanied by violent struggling and cries of "Oh! my heart! Oh! oh! oh!" In addition to being thus provoked, it was ascertained that these "attacks" had lately on one or two occasions occurred spontaneously, after a meal; and that the patient was frequently subject to terrifying dreams, out of which he would awake, gasping for breath. The field of vision was not tested, because the patient's eyes had been under atropine.

Remarks by DR. SAVILL.—Instances of this sort of hysterical attack are not frequent in the male subject, and careful inquiry was made with a view to ascertain the cause. Nothing could be discovered in the family history pointing to hereditary predisposition, though it should be borne in mind that the family history of this class is often very deficient, and that it is exceedingly rare to meet with the disease in the male without this kind of predisposition. However, it is quite possible that one or all of three causes were in ac-

tion in this case. 1. He had begun intercourse with the opposite sex at the early age of 16, and had lately had nocturnal emissions. 2. Both of the patient's eyes had been bandaged, and he had been placed in a dark corner of the ward for a period of seven weeks (Feb. 15 to April 5); and, though he had been subject to occasional "flutterings in the chest" prior to admission, he had only had the severe "attacks" since this treatment had been commenced. It seems to me probable that the introspective state induced by this long absence from the light had some connection with his hysterical condition. 3. In the same ward as this patient is in another, who is an undoubted hysterico-epileptic, with whom he has mixed rather freely; and thus the element of contagion or imitation is introduced. Which of these three causes predominated it is difficult to conjecture, but it is probable that they all tended to foster and develop the marked hysterical phenomena exhibited by this patient.

RECONSTRUCTION OF THE BLADDER.—At the recent Surgical Congress at Bologna, Drs. TIZZONI and POGGI showed a dog from which they had extirpated the bladder, and afterwards formed a new one by means of a loop of small intestine. A segment of gut had been removed, the two ends of the divided tube carefully stitched together, and the transplanted portion fixed by one extremity in the position of the neck of the bladder, whilst the other was closed by ligature. The ureters had next been isolated, fixed to the sides of the new bladder, and their lower ends turned into it. The new bladder, possessing a mucous surface lined with cylindrical epithelium, was found to work well when the nervous centres had become accustomed to the altered relations of parts. The operation was done in two sittings; in the first the loop of intestine was isolated, together with its mesentery, emptied of faecal matter, washed out with carbolized water, and tied at both ends, one of which was fixed in front of the neck of the bladder; in the second, which took place a month later, the ureters were detached from the bladder, the latter organ was removed, the lower end of the intestinal segment was cut through and fixed to the neck of the bladder, and the ureters adapted to the new bladder. For a week or so there was incontinence of urine, then gradually the animal acquired control over the organ, so that it could hold its water for an hour. Several dogs have since been operated on in the same way with success. The dog shown at the meeting passed urine naturally, and showed no sign of incontinence. Drs. Tizzoni and Poggi finally discussed the applicability of this procedure to the human subject.—*British Medical Journal*, May 4, 1889.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, JUNE 8, 1889.

YELLOW FEVER AND ITS PREVENTION.

At the Fourteenth Annual Meeting of the Arkansas State Medical Society, which was held at Pine Bluff, on May 28, DR. ALFRED NELSON, member of the College of Physicians and Surgeons of the Province of Quebec, and late a member of the State Board of Health of Panama, presented a paper upon the subject of "Yellow Fever." An experience extending over many years at Panama, Colon, Mexico, Cuba and Tampa, renders him specially fitted to write upon this subject. The honor, as being the first to recognize and cultivate the yellow fever germ and to use inoculation as a prophylactic, he accords to Dr. Domingo F. Revie, of Rio Janeiro. In this connection he refers to the faith of Dr. L. Girrard, late Surgeon-in Chief of the Panama Canal Company, in the protective power of inoculation, who inoculated himself and had a mild form of yellow fever which seems to have been followed by perfect immunity from that disease afterwards.

Dr. Nelson predicts that inoculation for yellow fever is destined to take equal rank with that for small-pox, and believes that a new era is at hand in the treatment of this terrible scourge. With reference to its pathology, he looks upon it as a blood disease pure and simple, and that except in the destruction of blood corpuscles there is often an absence of any other marked pathological evidence, death resulting from necræmia. With such prophylactic treatment and a proper quarantine surveillance, the travel and the commerce of the

nations, he believes, will be subject to little interruption. When the opportunity permits we shall be glad to place the entire paper before our readers.

IS THERE A SPECIFIC FOR CONSUMPTION!

It would be amusing, were it not so sad, to recount the many remedial measures employed against consumption. Their very number is a commentary upon the powerlessness of man to overcome this terrible foe. The very fact that they are all more or less successful in individual cases, emphasizes the impotence of any one remedy against the disease universally, and makes one doubt the likelihood of a specific ever being discovered. Only the prejudiced or ignorant would deny the incalculable service to humanity of Koch's discovery of the tubercle bacillus, since, by disclosing to the surgeon the real pathology of numerous affections, it has enabled him to deal with them the more successfully. But in the matter of finding a practical solution of the problem, how best to combat pulmonary tuberculosis, has it done much? It enables the physician to recognize the enemy he is fighting at an early stage, and thus renders him material aid. Nay, more! By disclosing the bacillus as the probable cause of the disease, it has pointed out the path that may ultimately lead to the heart of the enemy's citadel. In other words, it has shown that the measures which are to prove curative of phthisis, must be such as will either destroy the bacillus or overcome its deadly influence upon the human organism. More than this cannot be said.

Notwithstanding the unremitting efforts of physicians to find a specific cure for pulmonary tuberculosis, this has not been achieved. For this reason, it may not be time wasted, to glance at some of the means that have been essayed and are now in use.

These may be classified as general and local; the general being such, as it is hoped, will antagonize the constitutional effects of the disease, and by improving nutrition, help the system to limit the local destruction; while the aim of local treatment, is the reverse. It seeks to so modify or circumscribe the changes produced within the lungs, as to ward off the injurious effects upon the system at large that are sure to follow the unchecked progress of the local lesion.

Both of these plans are at times successful, but the best results appear to follow their union. Whatever plan of attack be adopted, or whatever the remedies employed, there should always be a careful hygienic management of each case. As it is assumed that this is understood, and we desire to mention only some of the most promising remedial measures in use, nothing further will be said on this score.

The French are particularly fertile in devising anti-phthisical modes of treatment, and one still giving success, it is said, although not much commented upon in the journals, is the subcutaneous injection of carbolic acid. It is best dissolved in glycerine. A 2 per cent. solution, and of this ten or fifteen minims are injected once or twice daily at first. The total daily amount thus administered may be gradually increased, without fear of toxic effects, it is asserted, if chemically pure acid be used. The acid is also given by the mouth by some. There is no possibility of saturating the system to such an extent as to destroy the tubercular bacillus which is peculiarly resistant, and hence the beneficial action of carbolic acid must be otherwise explained. This is to be found probably in its well-known power of lessening suppuration and putrefaction. Thus the fever due to absorption of the products of suppuration in the lungs would be lowered, fermentation within the gastro-intestinal tract would be checked, appetite and digestion improved, cough and expectoration diminished, sweating restricted, and consequently strength regained, which are precisely the results claimed for this treatment by M. Dujardin-Beaumetz and others.

Closely allied to the foregoing, and vastly more popular at present, is the internal administration of creasote. Jaccoud attributes to it decided virtue in counteracting the disastrous effects of absorption in the stage of softening; whereas von Bruun, Sommerbrodt and others after great experience with the drug, find it most beneficial in the stage of catarrh. It may be given in wine, cod-liver oil emulsion or in capsules. It is advised to begin with a daily dose of $\frac{3}{4}$ of a minim, which is to be gradually increased until the extreme limit of the stomach's toleration is reached.

Iodoform is likewise employed internally against phthisis, in pill-form, 1 grain being thus administered two or three times a day. Some favorable results have been reported of this agent

in conjunction with antipyretics. Great care should be exercised lest intoxication be produced.

Dr. C. T. Williams has experimented with phenyl-propionic acid in twenty cases of consumption of all stages, and with phenyl acetic acid in nineteen cases. The acids were dissolved in alcohol, one part in six, and of this ten to twenty minims were given in distilled water thrice daily. Of the cases treated with the former acid there was general improvement in 65.0 per cent., and improvement in the local manifestations of disease in 25.0 per cent. General improvement followed the use of the phenyl-acetic acid in 68.4 per cent., and local in 63.4 per cent.

These remedies are well borne by the stomach and may be administered for a long time. The phenyl-propionic acid seems to be the more suitable of the two for advanced cases.

Another drug from which excellent results are reported, is tannic acid in large daily amounts, forty to sixty grains. It was first proposed by MM. Arthaud and Raymond in consequence of their having found, by experiments on rabbits, that it lessened their susceptibility to inoculations of tubercular virus. Their observations have been confirmed by Ceccerelli, who found tannin exerted pronounced germicidal action in cases of tuberculosis of the bones and other accessible parts. In accordance with the views of Arthaud and Raymond, De-Viti-Demarco claims to have witnessed excellent results follow its prolonged administration in a number of cases, several of advanced phthisis. If given in moderate doses at first and gradually increased, it is tolerated by the stomach, and even improves appetite and digestion, cough, expectoration and night sweats; so that the medicine is certainly well worth a trial.

Of the effects of cod-liver oil, hyperalimentation, change of climate, etc., nothing need here be said.

Local medication is even more varied, and includes intra-pulmonary injections of solutions of iodine, carbolized camphor and the like, sprays of all possible antiseptic substances, the inhalation of ozone, oxygen and vapors of hydrofluoric acid, the wearing of respirators charged with divers sedative and antiseptic agents. But of all local measures account in detail can be given of only two. These are menthol and hot dry air. Fränkel and Rosenberg recommend the former by inhalation of its fumes at a tempera-

ture of 40° to 50° C. And in addition, Rosenberg advises intratrachial injections of a 10 per cent. solution in olive oil. To be efficient the Asiatic menthol must be employed.

The latest treatment, the one which seems *a priori* to come the nearest to being a specific, is the prolonged inhalation of air heated to a high degree, 250° C. (482° F.). Some accounts have already appeared in these columns of this measure, and Dr. Weigert's original communication to the *New York Medical Record* can be found in its issue of Dec. 15, 1888, together with a cut of his apparatus. The *rationale* of this treatment is based on the fact, that the tubercle bacillus is hindered in its development by temperatures either above or below that of the human body, 37.5° C. (99.5° F.) If, therefore, very hot air could be respired continuously, the bacilli ought to be destroyed, or at least deprived of their capacity for mischief. This being impossible apparently, Weigert has done the next best thing, viz.: made patients inhale air heated to 212° F. to 482° F. for two or more hours at a time twice or thrice daily. His published results are marvellous and warrant a careful investigation of his method. It commends itself for several reasons, one being that it can be used by the invalid at home. Not only do symptoms improve, but physical signs indicate the actual betterment of the local condition. To further the extended trial of this treatment, it is to be hoped that the instrument makers will place the apparatus on the market at such a price as will bring it within reach of all classes of patients.

THE DRAINAGE BILL.

Few subjects of State legislation have been more important than the Bill which was recently passed by the Legislature of Illinois, popularly known as the "Drainage Bill," and which received the signature of the Governor on the 29th of last month. Its purpose is the building of a ship-canal, which, in connection with the Mississippi river, shall form a great inland water communication between the Lakes and the Gulf of Mexico. Probably its importance to the Nation, and especially to the Mississippi Valley, in a commercial point of view, will hardly be over-estimated by its most sanguine promoters.

As a sanitary measure it has more than local interest and is worthy of a passing notice. Its

special importance to the city of Chicago can hardly be over-estimated. With a population numbering nine hundred thousand people, it was becoming a very serious question how properly to dispose of its sewage. The building of a ship-canal solves the whole problem—and, as it is believed, without detriment to other interests. A carefully conducted series of tests and observations has led our sanitary scientists to believe that the volume and velocity of the current will be such as to work its own purification and render it harmless to those who may be located in the vicinity of this new waterway.

With a tunnel projected four miles under the lake for the receiving of water beyond the limit of shore or surface pollution, and with such an outlet for its sewage—hardly more in these respects could be desired—and the ship-canal will doubtless prove to be one of the most important sanitary movements of the day.

A BRUTAL MURDER.

On the evening of May 4th, last, DR. P. H. CRONIN, a physician in the active practice of his profession, was called from his home and was driven to an unoccupied house at the Northern limit of Chicago and there murdered in cold blood. He went in answer to a request that he should minister to the needs of a laborer suffering from a severe accident—and in response to what seemed to be a legitimate demand of his profession, he went to his death. The motives which impelled to this foul murder we do not care to discuss, suffice it to say they neither compromised his individual or professional honor. Men may condone the crime of death by duel, perhaps; the assassin may enter a possible plea for leniency, but when in the name of suffering humanity a physician is thus lured from his home and brutally murdered, there are no words descriptive of such an atrocious crime, and there can be no palliation of such guilt.

THE ELECTION OF SECTION OFFICERS.

An old member of the Association, who joined it in 1859, writes to the Editor to say that he voted to change the election of officers of Sections, from the Nominating Committee to the Sections, but in his opinion there were gentlemen at a recent meeting who voted in several Sections, and

he is now sorry he originally supported the present method. The change, he says, was to insure that men specially devoted to the work in certain Sections should be elected by those familiar with the work.

Our understanding is that when the Association voted to change the system of election of the officers of the Sections, it was not contemplated that a member should vote in more than one Section, and the hour for the election of Section officers was intended to be fixed so that all Sections would vote at the same time. As time has progressed, it has become apparent that some safeguards must be thrown around the election of Section officers. It is thought that the most feasible plan is to have a Section register book, and on the day preceding the election that each gentleman intending to vote in a particular Section should be required to register his name.

The idea of Section elections was popular because it was thought the gentlemen in attendance on a particular Section were more likely to select a chairman who took a personal interest in the affairs of the Section than would the Nominating Committee, who were already overburdened with work.

The opinion was correct, but since men are as they are, it is necessary to see that Sections vote according to their real sentiment, and not "as packed." The requirement of registration would have the effect to correct any evil of the kind alleged to exist, and one of the most pleasant features connected with the Association is that, as at present constituted, the machinery for the correction of any real or suspected abuse is always at hand and can be easily applied.

EDITORIAL NOTES.

THE AMERICAN PUBLIC HEALTH ASSOCIATION will hold its Seventeenth Annual Meeting at Brooklyn N. Y., on Oct. 22, 23, 24 and 25, 1889. The Executive Committee have selected the following topics for consideration at said meeting:

1. The Causes and Prevention of Infant Mortality.
2. Railway Sanitation.
 - (a) Heating and ventilation of railway passenger coaches.
 - (b) Water-supply, water closets, etc.
 - (c) Carrying passengers with communicable diseases.

3. Steamship Sanitation.
4. Methods of Scientific Cooking.
5. Yellow Fever.

(a) The unprotected avenues through which yellow fever is liable to be brought into the United States.

(b) The sanitary requirements necessary to render a town or city proof against an epidemic of yellow fever.

(c) The course to be taken by local health authorities upon the outbreak of yellow fever.

6. The Prevention and Restriction of Tuberculosis in Man.

7. Methods of Prevention of Diphtheria, with Results of such Methods.

8. How far should Health Authorities be permitted to apply known preventive Measures for the Control of Diphtheria.

9. Compulsory Vaccination.

10. Sanitation of Asylums, Prisons, Jails, and other Eleemosynary Institutions.

Papers upon miscellaneous sanitary subjects not included in the above list will be received by the Executive Committee, subject to the requirements of the By-Laws.

The Secretary is Dr. Irving A. Watson, of Concord, N. H., to whom all communications should be addressed.

DR. S. P. MOORE, who was Surgeon-General of the Confederate States, died suddenly at his residence, Richmond, Va., on the 31st ult., of congestion of the lungs.

THE NEW HAMPSHIRE MEDICAL SOCIETY will hold its ninety-eighth annual meeting in Concord on June 17 and 18. The Councillors' meeting will be on Monday evening, June 17, at the hall of the G. A. R., at 7:30 P.M.

THE NEWPORT CITY COUNCIL has appropriated \$300 for the entertainment of the American Medical Association.

THE MISSOURI PACIFIC RAILWAY HOSPITAL at Independence will be removed to Kansas City, where it is the intention of the road to erect a \$40,000 building.

THE STAFF OF THE JOHNS HOPKINS HOSPITAL.—Dr. Wm. Osler has been appointed physician-in-chief; Dr. W. H. Welch, pathologist; Dr. W. S. Halstead, chief of dispensary; Dr. H. A. Lalleur, resident house physician; Drs. Harry

Taulmin and G. E. Clark, assistant house surgeons; Drs. Alan P. Smith, James Carey Thomas, Isaac E. Atkinson, S. C. Chew, Frank Donaldson, W. T. Howard, C. Johnston, T. S. Latimer, F. T. Miles, G. W. Miltenberger, L. McLane Tiffany, and H. P. C. Wilson, consulting physicians and surgeons.

DURING the past year the Pennsylvania Hospital treated 2,363 cases in its wards, 4,409 accident cases, and 7,616 out-patients.

BEQUESTS.—It is announced that the late Mrs. Sargeant, daughter of Dr. Oliver Wendell Holmes, has bequeathed to Harvard College \$10,000 as a memorial to her father, the income to be applied for the use of the anatomical department; \$25,000 for the general purposes of Harvard University; \$5,000 to the Massachusetts General Hospital; and in the event of her brother, Judge Holmes, leaving no issue, a further sum of \$25,000 to the Boston Medical Library Association.

A SCHOOL OF HYGIENE has been established at Naples.

PROF. CARL VOGT, the eminent biologist of Geneva, celebrated the fiftieth anniversary of his graduation as Doctor of Medicine on May 19.

PROF. TOMMASO VIRNICCHI, of Naples, one of the pioneers of modern surgery in Italy, died recently at the age of 64.

FATHER DAMIEN, the well-known Belgian priest, who labored so patiently for sixteen years in the leper colony of Molokai, in the Sandwich Islands, succumbed to the disease on April 10.

GALVANI ON ELECTRICITY.—Signor Dall' Olio, the assessor, recently paid a visit to the Communal Library at Bologna, Italy, and in the course of his search came on a book-case containing a number of volumes which had not been classified. Among them was found a hitherto unknown treatise by Galvani, on electricity.

M. PASTEUR will deliver the Croonian Lecture on the 23d inst.

MEDICAL EDUCATION IN TURKEY.—The Sultan has granted a subsidy of 500,000 piastres for the erection of a new clinical building and laboratories in connection with the Medical School at Constantinople.

BRITISH MEDICAL ASSOCIATION.—The fifty-

seventh annual meeting of the British Medical Association will be held at Leeds on August 13, 14, 15 and 16, 1889. The president-elect is Mr. C. G. Wheelhouse, F.R.C.S. The address in Medicine will be by J. Hughlings Jackson, M.D., F.R.S.; the address in Surgery by T. Pridgin Teale, M.B., F.R.C.S., F.R.S.; and the address in Psychology by Sir J. Crichton Browne, M.D., LL.D., F.R.S.

THE GERMAN DERMATOLOGICAL SOCIETY holds its first congress at Prague during the coming week.

CONSUMPTION IN THE GERMAN ARMY is greatly dreaded by the authorities since the recent Parisian Medical Congress pronounced that the disease was contagious. Accordingly, the German War Minister has decided that the chest of every soldier must be measured once a month. If the chest does not reach a certain breadth, and does not develop with drill and athletic exercises, the soldier will be disqualified as predisposed to consumption, and likely to infect his comrades.

SOCIETY PROCEEDINGS.

The American Surgical Association.

Annual Meeting, held in the New Army Medical Museum, Washington, May 14, 15, and 16, 1889.

(Continued from page 787.)

WEDNESDAY—MORNING SESSION.

DR. J. COLLINS WARREN, of Boston, read a paper on

THE EARLY DIAGNOSIS OF MORBID GROWTHS.

Reference was first made to the great desirability of some means of making an early diagnosis in cases of possible malignant disease. The attempt to make a microscopical examination of morbid growths before their removal dates back to the earliest period of microscopical histology. The pain and danger of inflammation attending the methods adopted led to their abandonment. Antiseptic surgery, however, now enables us to perform such an operation almost with absolute certainty of absence of inflammation. Local anæsthesia with ether spray or cocaine renders the exploration free from pain. The instrument which the author employs consists of a small canula, sharpened at the end. The calibre of the instrument varies from 2 to 5 millimetres. The in-

strument is used by gently rotating the canula between the fingers. After the instrument has penetrated the tumor to the desired depth, it is withdrawn a short distance, and then entered obliquely so as to cut off the column of tissue. The piece removed may be as large as 5 mm. in diameter and 3 cm. in length, or even larger. The fragment can be at once examined by means of freezing microtome or placed in alcohol and hardened. The operation can readily be performed at the physician's office and immediate diagnosis made. Several cases were reported illustrating the information obtained by the use of the canula. The instrument has been used in over 100 cases, with little or no discomfort to the patient and with satisfactory results. It has been used in abdominal tumors. It has been used in one or two growths involving the abdominal parietes and peritoneum, but not in deep-seated organs. The object of the author in bringing the results of his observations before the Association, was to show that modern improvements have made an old and discarded method not only practicable, but a valuable addition to our means of surgical diagnosis.

DR. F. S. DENNIS, of New York: I wish to protest against reliance upon this instrument in the diagnosis of malignant disease. I have never found pathologists willing to base a diagnosis of malignant disease upon the shreds of tissue removed by such instruments. More reliance is to be placed upon the clinical features than upon the microscopical appearances. Among these are age, situation of the tumor, the macroscopic appearance, pain, cachexia, lymphatic enlargement, hereditary influence, and finally the use of the harpoon. While the harpoon or cannula is a useful adjuvant, we cannot rely upon it absolutely in making the diagnosis.

DR. P. S. CONNER, of Cincinnati: I think that there is nothing more definitely settled than the difficulty of relying absolutely upon the microscopical examination in cases of supposed malignant disease. It is a confirmatory testimony of great value. In the instrument presented we have an additional aid to our means of diagnosis. While the points presented by Dr. Dennis are valuable, they do not aid much in the early diagnosis.

DR. R. A. KINLOCH, of Charleston, N. C.: It is a well established surgical principle that all tumors should be removed, so that the early diagnosis is perhaps not so essential. The question that arises is whether it would not be better to remove the tumor and make the diagnosis of its nature afterwards.

DR. W. H. CARMALT, of New Haven: In carcinoma and sarcoma the clinical features are, to my mind, a great deal more important than anything we can obtain from the microscope. Microscopical examination of different parts of the same tumor may present different appearances. An-

other point in regard to the use of the canula is the danger that the irritation excited by the instrument may convert a benign tumor into a malignant growth.

DR. WM. H. RICHARDSON, of Boston: I have seen this instrument used in many cases without bad effect, and the microscopists consider that they derive valuable information from examination of the plugs of tissue removed. We cannot make a correct diagnosis in the earliest stages of malignant disease from the clinical evidence alone, and it seems to me that in the early diagnosis this instrument affords valuable aid.

DR. L. McLANE TIFFANY, of Baltimore, read a paper on

FREE DIVISION OF THE CAPSULE OF THE KIDNEY FOR THE RELIEF OF NEPHRALGIA.

Four years ago the author had suggested the use of incision of the capsule of the kidney in the treatment of nephralgia. The patient, a woman *æt.* 49, white, married. Had had gonorrhoea and syphilis. She had had abscess of the pelvis opening by the vagina, the discharge continuing for two years. Three years ago she experienced, in the right loin, sudden severe pain, lasting for a moment. It was supposed to be due to the passage of a kidney stone. The attacks recurred at irregular intervals, the periods becoming progressively shorter and the pain more intense. No calculi had ever been voided. Blood had been seen at rare intervals. The pain always began in the right loin midway between the pelvis and the ribs. It then extended towards the middle line of the body, and down to the bladder and groin on the right side. Exertion was apt to induce it. Pressure on the right kidney caused acute pain, but no tumor could be made out. The urine was moderately acid, *sp. gr.* 1022, contained pus cells and a few red blood discs. There was no rise of temperature during the attacks.

The operation was performed January 12, 1889. The kidney, when exposed, moved freely during respiration. A deep stellate scar existed in the kidney, two inches from the lower end. No other abnormality was discovered. A sound was passed into the pelvis and a systematic exploration made, but no stone was detected. The capsule was then freely slit open for three inches. The edge of the cut gapped widely. The wound was then closed and an aseptic dressing applied. No urine passed by the lumbar wound. This soon healed, and since the operation, a period of four months, there have been no attacks of nephralgia.

DR. THEODORA A. MCGRAW, of Detroit: Three months ago I operated on a woman on the supposition that there was a renal calculus. None was found, but the capsule was freely slit and since the operation there has been no return of pain.

DR. LANGE, of New York: In one case of

severe pain recurring at irregular intervals, I operated with the expectation of finding a stone in the kidney, but none could be detected. I then proceeded in the manner described by the reader. The patient remained free from pain for three or four months. The attacks then reappeared.

DR. W. W. KEEN, of Philadelphia: I would like to refer to one source of error in the diagnosis of renal calculi, which has not been mentioned. I recently operated on a case of tumor of kidney in which, when the needle was passed into the substance of the organ, it gave a distinct impression of coming in contact with a stone. The tumor was malignant, and so adherent that it could not be removed. Subsequent examination showed that there was no calculus and that the needle must have come in contact with a calcareous vessel, of which there were several, or a mass of calcareous matter which was present.

DR. JOHN HOMANS, of Boston: I recently operated in a case in which there was a large swelling in the perineum, in a boy of 15 years. I removed, by perineal section, thirteen stones from the urethra. The urethra would admit my forefinger. There was also a swelling in the loin, which did not disappear after the operation. Three weeks later I opened the kidney through the right loin. I found a considerable quantity of pus, but could detect no stone, although I am not sure that a stone may not have been present.

DR. J. M. BARTON, of Philadelphia, read a paper on

DIGITAL DIVULSION OF THE PYLORUS FOR CICATRICAL STENOSIS.

(See page 799.)

DR. R. A. KINLOCH, of Charleston, S. C.: I have no personal experience with this operation. We must accept the testimony of reliable men, but I cannot understand how an organic stenosis of the pylorus is cured by a single dilatation. This is not the case with organic stenosis in other parts, as the rectum and œsophagus. I am inclined to believe that where the benefit has continued for any length of time, the organic change has been slight. I can understand how benefit could be expected if the wound were kept open and the stricture systematically dilated.

DR. M. H. RICHARDSON, of Boston: The mortality of gastrotomy, as a primary operation, is extremely small. I have also found, from sixty dissections, that the longitudinal incision between the greater and lesser curvatures made the best incision for reaching either the pylorus or the cardiac extremity of the stomach. The shortest incision was one inch, but the incision usually required was two or three inches.

DR. J. EWING MEARS, of Philadelphia: While it may not be easy to explain the results obtained by digital divulsion of the pylorus, there can be no question as to the beneficial results. The evi-

dence of reliable operators certainly indicates that it is a proper operation and attended with successful results. This operation should always be performed in preference to pylorotomy.

AFTERNOON SESSION.

DR. THEO. A. MCGRAW, of Detroit, read a paper entitled

A CONTRIBUTION TO THE HISTORY OF GUN-SHOT WOUNDS OF THE ABDOMEN.

Reference was first made to a case of gun-shot wound of the abdomen operated on by Dr. R. Abbe, of New York, July 8, 1886, in which, four hours after the accident, adhesions of the intestine to the abdominal wall were found, forming a cavity containing extravasated feces. The adhesions were broken up, and four holes in the bowel and one in the bladder were closed. Suppression of urine and death followed. In August, 1887, the author was called to a case of gun-shot wound of the abdomen, fourteen hours after its occurrence. At the operation it was found that adhesions had formed, shutting off the peritoneal cavity. These were broken up and eight perforations of the bowel found. Five of these had become so occluded by lymph as to be detected with difficulty, and no discharge could be forced thro' them. Four feet of the ileum were excised. The patient died twenty-six hours after the operation. A study of these cases led the reader to suggest that under such circumstances the drainage of the cavity would be the best plan to adopt. The artificial anus or fecal fistula could then be operated on at a later period. The question arises, whether or not these cases of early agglutination are sufficiently numerous to warrant our making them the point on which the treatment of all cases of penetrating wounds of the abdomen, over six hours old, must turn. This question can not be decided at present.

A review of the approved methods of treating gun-shot wounds of the abdomen was then taken up. The great danger has been shock. The shocks had depended, 1st, upon the time occupied in operating; 2d, upon the amount of evisceration; 3d, upon the number and the nature of the injuries to be repaired; 4th, upon the chilling of the intestines; and 5th, possibly upon the long-continued anæsthesia. In discussing the subject the following propositions were considered, many of them based upon experiments upon dogs and sheep:

1. The gravity of an injury of this kind depends partly upon the size of the missile.

2. Gun-shots which enter the abdominal cavity pass in a nearly absolutely straight line from the orifice of entrance, through the peritoneum to that of exit, or to their final stopping-place in the viscera. All apparent deviation of bullets fired

into the abdomen from a direct path are due to changes in position subsequent to the shooting.

3. An incision made directly in the course of the ball, will give the shortest route to the injured viscera.

4. The contents of the bowels may be made to discharge through an open gun-shot wound by manipulation and pressure.

5. An empty condition of the alimentary canal is most favorable to healing. To secure this it may be proper in some cases of injury of the bowel immediately after a hearty meal to evacuate the contents of the stomach by means of a siphon.

6. Agglutination and limitation of the morbid processes consequent upon gun-shot wounds may take place as early as the sixth day.

7. Senn's method of hydrogen-gas insufflation, however admirable in recent cases, should be used with great caution in cases four hours old, and especially in those made by small bullets.

8. The dangers of the operations for penetrating gun-shot wounds of the abdomen are directly in proportion to the length of the operation and to the amount of the evisceration. The duration of the operation may be lessened, 1st. Making the incision over the line taken by the ball, or if it has passed from before backward, over the point of entrance. 2d. By limiting the examination of the viscera strictly to such of them as may have been in the course of the ball. 3d. By suturing wounds of the intestine, wherever it is possible, instead of excising them. 4th. By omitting all operative procedures, even suture, in wounds which have become so thoroughly occluded by plastic material that the contents of the bowel cannot be pressed through them. 5th. By operating first on those wounds which imperatively demand it and leaving to the last those which may recover without operation. 6th. By never eviscerating a patient, except, first, when hæmorrhage is otherwise uncontrollable; and secondly, when there is a discharging wound which cannot otherwise be found. The evisceration of a patient is as dangerous as any gun-shot wound of the intestine which cannot be made to discharge its contents by manipulation or pressure can possibly be. There are cases where evisceration is necessary, but the author protested earnestly against the habit of eviscerating patients suffering from gun-shot wounds of the abdomen as a matter of routine. We are not warranted in turning a man inside out and subjecting him to frightful dangers in the mere fear that there may still be an undiscovered wound, when all the symptoms which ought to indicate such a wound are absent.

9. In cases of these wounds in which the patients may be too weak to undergo any radical operation for their repair, efforts for their relief may be made by incision and drainage, and in some cases by attaching the injured intestine to

the abdominal wall, as in gangrenous hernia. This procedure, occupying but little time and making no draft upon the strength of the patient, may offer a hope of recovery which would not be possible under the expectant mode of treatment.

DR. D. W. YANDELL, of Louisville: The statement in regard to the course of balls is new to me. A number of cases which I have seen had led me to believe that balls entering the abdomen might deviate very greatly. I am not altogether prepared to accept the statement at present. In one case, in which the pistol was held near the individual and in a straight-line, the ball entered above the symphysis pubis, and was found below the spleen, having wounded intestines in its course. The recommendation that in the extreme cases, where the patient is greatly exhausted, the wounded intestine be secured at the abdominal incision, is certainly conservative, and it would seem to me to be wise.

DR. C. B. NANCREDE, of Philadelphia: There are such a number of cases on record in which it was supposed that the balls were deflected, that I think that there can be no doubt that this occurs occasionally. In regard to the incision, from my experience with both the median and lateral incision I am forced to the conclusion that unless we are certain that the ball has followed an antero-posterior course, the median incision is to be adopted in every case, with rare exceptions. I suppose that Dr. McGraw means by evisceration, removal of the intestines *en masse*. It makes a great difference, as far as shock is concerned, whether the intestines are removed all together or simply an inch brought out of the opening, immediately replaced and another portion examined, at no time exposing a large portion of the bowel. So many cases have been recorded in which death was the direct result of overlooking a single wound of the viscera or blood vessels, that the only safe rule is to make a thorough examination before closing the abdominal incision.

DR. J. EWING MEARS, of Philadelphia: The median incision is, I think, the one which should be adopted. It can be extended any desired distance, which cannot be done with the lateral incision. By the median incision the entire abdominal cavity can be inspected. In regard to what has been termed evisceration, I think that it is better to permit the patient to die without operation than that an incomplete or imperfect operation should be performed. I think that the surgeon would be almost criminally culpable if after subjecting the patient to the dangers of an abdominal section he closes the abdomen without satisfying himself by thorough examination that he has found every wound that could have been inflicted. It is not necessary to turn all the intestines out. It is sufficient to slip them through the hands, subjecting them to careful inspection.

DR. R. A. KINLOCH, of Charleston: After the

abdomen is opened in a search for wounds I think that every wound should be closed. We cannot say that one wound is of less importance than another.

DR. W. W. KEEN, of Philadelphia: As regards the line of incision, we should make a distinction between stab wounds and gun-shot wounds. In the former case I think the incision should be made at the point of wound, while in the latter the almost invariable rule should be the median incision. I can but agree with previous speakers that after we have opened the abdomen no case is properly treated if we leave by any possibility a single wound. Every wound should be sutured.

DR. C. H. MASTEN, of Mobile: In regard to the course of balls, I treated one case in which the ball entered one inch to the right of the umbilicus, made nine openings in the intestine, passed down through the bladder, out through the prostate, and lodged near the tuber ischii on the left side. The spinal column had not been injured.

DR. F. S. DENNIS, of New York: I believe that it is a rule, without exception, that the median incision should be made where we are going to sew perforations in the bowel, or stop hæmorrhage in the abdominal cavity. The point of first importance is the control of hæmorrhage. The median incision will permit the surgeon to enter the peritoneal cavity in half a minute.

DR. STEPHEN H. WEEKS, of Portland: I have not heard allusion in regard to the use of Dr. Senn's method. He laid stress upon two points, first, the use of the gas in determining whether perforation had occurred, and second, in locating the openings in the bowel. It seems to me that this latter is a valuable point.

DR. STEPHEN H. WEEKS, of Portland, Me., read a paper on

DRAINAGE AND DRAINAGE-TUBES IN THEIR APPLICATION TO THE TREATMENT OF WOUNDS.

He referred to the great importance of drainage, and after alluding to the various methods proposed for securing it, described a new form of absorbable drainage-tube prepared from the arteries of animals. The arteries used are those of the ox. They are separated from their sheaths, cut into tubes 4 or 5 inches long. They are then boiled in water for about five minutes. This sterilizes them and hardens their coats. Holes are next cut in their sides and they are passed over glass rods of different sizes, according to the size of tube desired. They are now placed in corrosive sublimate solution, 1:100, and allowed to remain ten minutes. Then they are placed in alcohol, 95 per cent., and at the end of twenty four or forty-eight hours the glass rods are removed, the tubes being kept in alcohol until needed. These

tubes are unirritating to the tissues, they are absorbed in from five to seven days and drain the wound perfectly.

THURSDAY, THIRD DAY—MORNING SESSION.

DR. JOHN HOMANS, of Boston, reported

A SUCCESSFUL CASE OF NEPHRECTOMY FOR THE REMOVAL OF CANCER OF THE RIGHT KIDNEY.

The patient, a woman of 50, for a year had suffered with frequency of micturition. The urine had been dark and bloody at times. For three years she had suffered from indigestion. The tumor had been discovered in 1887 in the right iliac region, and since July, 1888, it had grown rapidly. It filled the right iliac region and more or less the umbilical and pubic regions. On palpation large irregular nodules were felt, and in some parts there was fluctuation. Laparotomy was performed January 21, 1889. The incision was made in the linea alba and was 4 inches in length. The tumor was exposed, and in the upper part was seen the remaining portion of the kidney and two large renal veins. These were tied with silk and the ureter was next tied and divided, and then the pedicle was readily ligated. The tumor was removed, a glass drainage tube introduced, and the wound closed and dressed with iodoform gauze and absorbent cotton. The tumor measured 6 by 9 inches and weighed 53 ozs. There was very little shock. The amount of urine since the operation has varied between 10 and 57 ozs. and has been gradually increasing. There was but little discharge from the drainage tube, which was removed on the fourth day. One month after the operation an abscess was opened in the right lumbar region. A slight swelling and some tenderness still remains in the right loin; whether these are wholly inflammatory or due to a recurrence of the growth cannot at present be determined. The patient is rapidly gaining strength.

The experience of the author led him to say that a large renal tumor which cannot be diminished in size by tapping (he would consider one weighing 1 lb. or more a large tumor), can most conveniently be removed by an incision through the linea semilunaris or in the linea alba. Small tumors and those that can be diminished may be removed by the lumbar incision. In cases of moderate-sized kidneys disorganized with pus, or tubercular or containing calculi, the lumbar incision is preferable.

DR. FREDERICK E. LANGE, of New York: In cases where a large tumor of the kidney is to be removed and where it is desirable not to open the peritoneal cavity, I have found a trap-door incision with resection of one or two ribs if necessary, give ample room for operation. I have operated nine times, but never for neoplasms. With free incision and open antiseptic after-treatment I re-

garg extirpation of the kidney, even in cases of large tumors, a comparatively safe operation.

DR. M. H. RICHARDSON, of Boston: There is a frequent anomaly of the vascular supply of the kidney which should be borne in mind in operations. Instead of one renal artery there may be three or even four arteries. If such a pedicle is ligated *en masse*, there is danger of slipping of the ligature and hæmorrhage. This is obviated by tying the pedicle in several sections.

DR. LEWIS S. PILCHER, of Brooklyn, read a paper on

THE QUESTION OF THE ANTI-TUBERCULAR POWER OF IODOFORM, WITH A SUGGESTION FOR A MORE EXACT CLINICAL TESTING OF THE SAME.

The paper first called attention to the different results obtained by the application of iodoform to tubercular tissues, according as the results were derived from clinical experience or from observation of tubercular affections artificially induced in animals. The following case was a contribution to the study of this question:

A girl æt. 13, with a family history of tuberculosis, came under observation with an infiltrated and ulcerated patch on each leg; there was also on each thigh an infiltrated patch without ulceration. The disease was of three months' standing. The diagnosis of tuberculosis of skin was made. The patch on the right leg was excised and microscopical examination confirmed the diagnosis; tuberculous nodules with bacilli were found. The patches on the thighs were also excised and healed without further treatment. Bismuth was applied to the patch on the right leg and healing progressed satisfactorily. It was then determined to apply skin grafts. The sore was curetted, the grafts applied and did well for a time. Later the epithelial elements broke down and a number of small ulcers formed. At the base of each ulcer was found a particle of bismuth. Portions of the tissue removed, however, showed no bacilli. No iodoform had been employed. Boracic acid ointment and the occasional application of nitrate of silver were now ordered. The ulcer on the left leg was curetted December 10, 1888, sprinkled with iodoform and covered with absorbent cotton. It rapidly healed, and on January 25 a wedge-shaped piece was removed and examined. It was entirely free from evidences of tuberculosis. A soft natural skin has since formed.

DR. W. H. PANCOAST, of Philadelphia, made some brief remarks on the following topics:

1. That the so-called metacarpal bone of the thumb did not belong to the metacarpal group; that its method of development clearly placed it in the class with the phalanges.

2. He next exhibited and described his urethrotome, which he had used with satisfaction for twenty years.

3. A delicate knife which he termed the therapeutic knife, employed for making numerous minute punctures in an inflamed part for securing an antiphlogistic effect.

4. A gun breech which had remained for some time unsuspected in the superior maxillary bone of a boy.

5. The use of black silk bandages and black adhesive plaster as adding greatly to the neatness of a dressing.

6. The use of iron dyed black silk ligatures.

7. His method of treating varicocele by passing a silk thread through the scrotum between the vas deferens and the veins, returning it through the same opening in the skin but in front of the veins, passing the ends of the ligature through holes in a metal plate and tying tightly. The cure is complete in three or four days.

The committee appointed to take action in regard to the death of Dr. S. W. Gross, presented the following:

WHEREAS, It has pleased the Almighty to remove from our midst Dr. Samuel W. Gross, who assisted in founding the American Surgical Association and contributed by his example and work largely to its success, who as a teacher was enlightened and impressive, as an author was accurate and original, as a surgeon was sound in judgment, rich in clinical experience, skilled in manipulation, and as a Fellow was genial and courteous; therefore, be it

Resolved, That the Association deplores his death as an irreparable loss, and directs that a copy of the foregoing be spread upon its minutes and forwarded to his bereaved family. Signed,

D. W. YANDELL,
P. S. CONNER,
J. EWING MEARS.

OFFICERS FOR ENSUING YEAR.

President—Dr. D. W. Yandell, Louisville, Ky.
Vice-Presidents—Dr. Claudius H. Masten, of Mobile; Dr. C. B. Nancrede, Philadelphia.
Secretary—Dr. J. R. Weist, Richmond, Ind.
Treasurer—Dr. P. S. Conner, Cincinnati.
Recorder—Dr. J. Ewing Mears, Philadelphia.
Council—Drs. John S. Billings, L. McLane Tiffany, W. F. Peck and F. S. Dennis.
Chairman of Committee of Arrangements—Dr. J. S. Billings, Washington.

The following were elected members: Dr. Stephen H. Weeks, Portland, Me.; Dr. Robert F. Weir, New York; Dr. John Homans, Boston; Dr. Lewis A. Stimson, New York; Dr. Frederick E. Lange, New York; Dr. Lewis S. Pilcher, Brooklyn; Dr. Levi Cooper Lane, San Francisco; and Dr. Arthur T. Cabot, Boston.

The Association then adjourned to meet in Washington the second Tuesday in May, 1890.

Philadelphia County Medical Society.

*Stated Meeting, April 10, 1889.*THE PRESIDENT, W. W. KEEN, M.D., IN
THE CHAIR.DR. GEORGE ERETY SHOEMAKER read a
paper on

EARLY RECOGNITION AND TREATMENT OF MALIGNANT DISEASE OF THE UTERUS.

In considering this subject two general stand-points present themselves; that of the pathologist and that of the clinician. While of course both are interdependent and of great importance, it is proposed in these remarks to give special attention to the recognition of cancer by the means available to the practical physician who is called upon to make up his mind during the life of the patient what the trouble is and what is to be done for the patient's good.

The importance of the subject, since every physician finds a large part of his practice to be among women, is shown by the mere statement that out of 4,600 cases of diseases of women reported by Emmett, 113 from all classes of society had malignant disease of the uterus, or 2.45 per cent.

As in the case of malignant tumors of other portions of the body, their existence in the uterus in advanced stages is easy to determine, though some obscurity as to the variety may remain. The peculiar sharp, inconstant, lancinating pain in abdomen, back and thighs; the discharge of watery fluid with a characteristic odor; the presence of hæmorrhage and cachexia; form a group of symptoms which are conclusive almost without an examination; while even the practitioner who almost never makes a vaginal exploration would not fail to recognize an advanced growth on touch and inspection.

Whatever be the nature of the growth, the immobile uterus, the cervix large, hard and patulous; the abundant nodules, hard, inelastic, immovable; the extensive ulceration, the probable presence of exuberant granulations if not cauliflower excrescences, with their friable, easily bleeding characters, will be at once recognized.

But it is in precisely these far advanced cases that diagnosis is least important, for the palliation from operative treatment is greatly less than in earlier stages. The time to diagnose cancer is in the very beginning, when thorough removal can be made, and it is just here that the average practitioner is at fault. Perhaps through lack of confidence in his own powers of diagnosis, perhaps from a general impression that no benefit would be derived from treatment, perhaps from a personal distaste for such examinations and long disuse of them except before and during labor (I say before and during labor, not

after labor, for it would seem, as far as the writer's observation goes, not to be a habit among practitioners to satisfy themselves, by systematic examination at the end of every puerperal period, that no serious lacerations or displacements are left to produce future trouble, from whatever cause it may be, cases of malignant disease of the uterus are too often allowed to drift along through a most important period unrecognized. Even if not a specialist, if a practitioner will take the trouble to do his very best he can learn much in such cases. Let him take plenty of time, go to the trouble of securing a good light so that he can see clearly, let him see the case on his office chair if possible, at any rate not with the hips half buried in a bed, placed as far as possible from a heavily curtained window.

It is, however, true that in a few cases malignant disease will make considerable advance without giving rise to symptoms enough to bring about an investigation.

Early symptoms.—Bleeding in most cases first attracts attention. If menstruating the woman will lose more at her periods or may bleed between them, as she does from many other causes. If she has definitely ceased to menstruate, the occurrence of hæmorrhage, even though slight, should always lead to immediate examination; for while the cause is more likely to be fungous endometritis or a fibroid or polypoid tumor, evidence of cancer may be found. It is not a trifling matter to suggest that the results of this examination should be put upon record, with the date, even though apparently negative. The discharge is irregular, increased by exertion, and may consist either of bright blood which will clot, or of a bloody watery fluid, with or without odor. The patient may at the same time have a free leucorrhœa, of independent origin.

The nature of the disease may not be suspected by the woman, who may present every appearance of florid health, and whose previous life may have been more than usually free from disease. Usually, however, there will be some evidence of impaired vitality and loss of tone; though a true cachexia, with its dead-white, or sallow, or straw hue of the skin, its pinched and peculiar expression, belongs to a later period of the disease, when there is considerable constitutional change.

The very earliest symptom is in some cases *pain* while others will pass through all stages of the disease and remain remarkably free from it. The writer has in mind a case of his own, where the diagnosis of advanced epithelioma does not admit of question, and where pain has never occurred in any considerable degree.

In another case under his observation, but slight pain is present and that not characteristic.

It is said to be generally more severe in epithelioma than in the interstitial forms of disease.

and more apt to be severe when the infiltration passes beyond the cervix to the body of the organ. Infiltration of surrounding pelvic tissues involves pressure on sacral nerves, which occasions severe pain in one or both hips and down the backs of the thighs; but the pain may come from nipping of terminal fibres of the sympathetic system within the cervix or body of the organ. Persistent pelvic pain, especially if lancinating and extending to the loins and the back of the thighs, should excite suspicion of malignant growth, particularly in women near the menopause. The offensive watery discharge speaks of disorganization of tissue and is not often a very early symptom, though characteristic when found. Offensive leucorrhœa from other causes is not uncommon, but there is no smell like a cancer smell. The absence of odor is by no means indicative of the absence of disease, and this is true of *every other* single symptom.

Thus far there is nothing to suggest the variety of growth which may be present. Examination reveals more exactly the condition of affairs.

The malignant growths which may involve the uterus are quite variously classified, but may be given as follows in their order of frequency:

Epithelioma:

Encephaloid or "soft" cancer:

Sarcoma:

While scirrhus and colloid cancer (or as it is now classified by some writers, myxo-sarcoma) may be described as rare.

Signs.—In epithelioma, the finger in the vagina usually finds the cervix harder than normal even in early stages of the disease. The growth begins either in the mucous membrane lining the cervical canal, or on the vaginal portion of the cervix. If the former, the only fact discoverable by the finger will be an enlargement and hardening of the neck, while the os is enlarged and irregular. Ocular inspection may show nodules within the cervical canal, perhaps covered by an ashy deposit. Their color ranges from pale yellow to dark red, according to the amount of blood infiltration. Their hardness is quite characteristic. The mucous membrane is bound down and immovable. Goodell has suggested that in such a case the introduction of a sponge tent will materially aid the diagnosis.

Says he:

"If the cervix soften down, the os dilate, and the mucous membrane become movable under the expansion of the tent, the disease is probably a benign one. If, on the other hand, the cervix remain hard, its mucous covering immovable, and the os unyielding, the suspicion of malignancy will be confirmed." (*Lessons in Gynecology*, p. 224.)

The uterus meanwhile may remain movable, and scarcely, if at all, enlarged, as the disease extends; while, as a rule, advancing no higher

than the cervical canal, a rough friable mass occupies that passage, which breaking down in the centre, may leave the cervix excavated, so as to form a large cavity extending to the internal os. The edges of this cavity are often sharp, hard and irregular. Pain may still be almost entirely absent.

When beginning at the vaginal portion of the cervix, externally as it were, the epithelioma assumes one of two forms, either appearing as an ulcer with irregular edges and an excavated base covered with ashy-colored detritus, or else taking the form of a fungous mass. This mass of friable, rough granular feel may be spread out over the cervix, or spring from it as a pedunculated outgrowth, forming the so-called cauliflower excrescence. This form when present is sometimes very easily recognized by the fact that it feels as though portions could be broken off. A polypus is usually softer and smoother, and a papilloma is less fragile, less irregular, and may be enveloped by a continuous epithelial coating.

Two cases, seen for the first time within a few weeks of each other, may be cited in illustration, one of fungous-like epithelioma, and the other of fibrous polypus. Both women were beyond the menopause a few years. Both had some bladder irritation and pelvic uneasiness, but no pain. Both had borne children. Both had leucorrhœa. One of them had seen a little blood irregularly, and was pallid. In both, the only abnormal structure discoverable by the finger was a round pedunculated growth of about the size of a walnut, which grew from the cervix. The pedicle in each case was about half an inch through, was distinct, like the stem of a toadstool, but shorter; while the body of the growth in each case was roughened and firm.

Diagnosis of malignancy was made in one case at once, reliance being placed on the following points: The uterus was not normally movable, and was slightly enlarged, as made out bimanually; the pedicle grew directly out of the lower lip of the cervix, and above it could be felt the os distinctly. No other growth would have been situated here. A polypus or a papilloma of that shape would have come out of the os. The whole tumor except the pedicle was covered by nodules the size of those on a blackberry, and was not smooth to the touch. No impression of flexibility or elasticity was conveyed to the finger, the whole growth having that indescribable dense feeling which is easily recognized as belonging to this class of growths.

At the operation, as soon as the lower lip was cut away with the scissors, and the cavity of the cervix thereby opened up, it was found filled with very firm cancerous nodules of the size of a buck-shot, or larger. This, of course, confirmed the diagnosis, but could not previously have been determined, for the os was not dilated at all.

In the other case, however, though the general resemblance was so great, the diagnosis of benign tumor rested on the fact that the pedicle, springing from somewhere within the uterus, came out of the os and expanded as a perfectly smooth stem, covered by smooth membrane, and giving the impression of a tough, homogeneous fibrous structure, which would bend and not break. The body of the growth was resilient, though firm, and indented on the lowest surface like a papilloma. The symptoms did not suggest malignancy, though they did not exclude it. They never do.

But it is in the very early diagnosis of epithelioma that we are most concerned. Though doubted by some writers, as Byford and others, there is very strong evidence to be brought forward in favor of the local and, as it were, traumatic origin of epithelioma. It seems in many instances to be a perverted effort of nature to repair an injury, as has been said by Emmet, and this gives a much greater significance to unhealed and irritated lacerations. Whether the theory of traumatic origin be accepted or not, it is not to be ignored that a man who has given as much attention to diseases of the cervix as has Emmet, should be able to say that he had never seen a case of epithelial cancer in a woman who had not at some time been impregnated.¹ Hofmeier, however, in his statistics of cancer of the uterus, speaks of 39 nulliparæ among a total of 812 cases.

The tendency of cicatrices to become the seat of morbid growths is well-known. The frequency of unrepaired lacerations, and the profound alterations of structure which often follow them, have led to careful microscopical study of the tissues which have been removed in the operations for repair, with the result of finding, as reported by Cushing, of Boston (*Annals of Gynecology*, April and June, 1888, etc.) to the Ninth International Medical Congress, several cases of undoubted cancer, which could not have been diagnosed from glandular hyperplasia and erosion by either sight or touch alone. This author has urged with great pertinency, that some cases of bleeding erosions in women of 50, or thereabouts, are undoubtedly beginning epitheliomata, and as the removal of such surfaces is a slight operation, it is worth doing and may be of the greatest importance. (*Annals of Gynecology*, June, 1888, preliminary article.) This he urges without admitting, as has been claimed by Ruge and Veit, that the transition stages of erosions into epitheliomas may be demonstrated, but the fact remains that some erosions are epitheliomas, and we cannot always tell which. It is unreasonable to say that every erosion should be removed by the knife or scissors, for we know most of them can be cured by proper treatment; but it seems justifiable, to say the least, to remove thoroughly all

those which are stubborn in resisting well-directed treatment.

In doubtful cases, much light may be obtained by removing a wedge-shaped piece for microscopical examination; for while malignancy cannot be thus excluded, it may be found. It cannot thus be excluded, for it has been shown that cases showing clinically evident signs of malignancy, and so diagnosed by excellent authority, still have failed to show typical characters under the microscope. (*Cushing loc. cit.*)

No harm is done by this excision of a piece. The bleeding would be readily controlled by an alum tampon properly inserted at the time, and if the disease should prove to be malignant under the microscope, operation would immediately follow.

ENCEPHALOID CANCER.—The early diagnosis of this disease is rarely, if ever, made. By the time obvious changes have occurred the disease has advanced so far as to have seriously infected neighboring glands and tissues, so that no thought of surgical removal is possible. This is particularly true when the body of the uterus is first involved. The usual point of origin is the lower end of the cervical canal in the submucous tissue. Ulceration destroys the mucous membrane, and vascular granulations appear. The whole cervix becomes hard, irregular and knotty, in a way that is simulated by no non-malignant disease. Irregular friable vegetations spring up and cover the whole lower end of the cervix. These bleed freely on being touched, and exude a watery offensive fluid, like the washings of raw beef. The further progress of the case, the infiltration of surrounding tissues and organs, the breaking down and sloughing, until all semblance of the normal configuration of the parts is lost, need not be here detailed.

Sarcoma of the uterus is not often met with. Its accurate diagnosis, either early or late, is usually impossible without the microscopic examination of a piece of sufficient size to show not only characteristic cells, but their relations to surrounding tissue. Scrapings may not be sufficient. It occurs in two forms: (a) *Circumscribed*, when it strongly resembles fibroid tumor, and constitutes the class formerly known as "recurrent fibroid." (b) *Diffuse*, when it involves the whole uterus, together with surrounding tissues and organs. The cardinal points in the diagnosis of sarcoma are, rapid growth, a few months only at times; cachexia, especially significant where there has been comparatively little loss of blood; extreme pain; the presence of serum in the freely flowing blood (which is not found in non-disintegrating fibroids, but is found in carcinoma); the soft, brittle, brain-like character of proliferating portions, if any can be felt. This separates it from carcinoma. Carcinoma is not so apt to form a circumscribed tumor. But, after all, the

¹ Principles and Practice of Gynecology. Page 509.

² Zeitschr. f. Geburtsh. und Gynäk., vol. x.

practical point is the diagnosis of malignancy, for early removal is the rule in any form of growth.

Scirrhus and myxo-sarcoma present no early signs of individuality which need be considered here.

After all, there remain certain cases in which the early diagnosis of malignancy is practically impossible, and the decision for or against a radical operation becomes a matter of great anxiety to the physician. When the disease is not accessible at the cervix, but begins within the body of the uterus, or even at the internal os, the excision of a piece for examination is not practicable in ordinary cases. One is then obliged to wait, perhaps too long, for some definite guide. Such a case has just been troubling the writer. The uterus is small and soft. Pain is slight and recent. A most intractable pruritus, of two years' standing, is due to the cervical discharge. Except for a lining membrane too dark in color, the lower part of the cervix is about normal in structure; it is excavated, and admits the whole of the first phalanx of the finger, but a peculiar laceration partly, if not wholly, accounts for its patulous condition. The lining of the uterus is smooth, but just at the internal os, beyond the point where the finger-tip stops, the curette finds little elevations, entirely too tough and gritty to make the mind easy. This patient has been closely watched and carefully studied. I shall proceed at once to remove the suspicious tissues, but the decision has not been an easy one to make.

Even later on, diagnosis may not be easy.

In another case at present under the writer's care, the portion of the uterus accessible from the vagina is soft and not nodular. There is no bleeding, and no discharge, pain, or other symptom which cannot be partially accounted for by a well-defined stricture of the rectum and its consequences. Bimannual examination is practically negative, since the true pelvis is choked by a smooth mass cementing in the uterus. The vaginal roof is hard, smooth, unyielding, suggesting the results of a late confinement which had inflammatory sequelæ, but the stricture helps to throw light on the case. Even this is smooth, and not typically cancerous, so that the aggravating word "probable" must go down with the diagnosis of malignancy. Long since did observation show the writer that the brilliant and dogmatic diagnosis of tumors flourishes chiefly in the clinical lecture-room and in the journal reports of just completed operations.

Treatment.—This is, of course, eminently surgical. As in cancer of the breast, not every case of malignant tumor of the uterus is to be operated upon by any means. There is room for the exercise of much judgment. One fact, however, is established beyond all question; it is that years of life and great suffering may be saved by early and radical removal, especially of epitheliomas.

If the operation is not thorough, life is shortened by it, except in the later stages.

If the disease is still confined to the cervix and lower uterine segment, several operations may be made. One of the best is the amputation of the vaginal portion of the cervix (Schroeder so far), and then with a knife cutting out a cone-shaped piece from the body of the uterus, including the canal, following with the Paquelin cautery. This is the operation of Baker, of Boston. Emmet uses scissors, knife, and curette with Simon's spoon, to shell out the diseased tissue, and then, as far as possible, draws mucous membrane over the raw surfaces by stitches. Most operators apply either the Paquelin cautery or, as recommended by Marion Sims, chloride of zinc as a caustic, after as much tissue as possible has been cut away. The dangers after such operations are from hæmorrhage and septicæmia, but the mortality is small. There is a very strong ground for belief that the actual cautery lessens the risk of subsequent development of disease. It certainly retards it more than the knife if all is not removed. Total extirpation of the uterus is coming into prominence in this connection, and statistics are rapidly accumulating. By the use of compression forceps for the lateral vessels, instead of ligatures, the mortality of the operation has been enormously diminished in good hands, but the place of the operation in surgery of the uterus has not yet been definitely settled. There is very little to show its advantage in ultimate results over Schroeder's method of high amputation of the cervix, where the disease usually lies, especially if followed by clearing out the interior of the uterus, as advocated by Baker, of Boston. If the disease is just beginning, the safer operation is just as thorough. If the disease is further advanced, to remove the entire uterus is not to remove surrounding infected glands and tissues, and there are no statistics which show conclusively that the liability to return is less than in the other operation. On the contrary, while recent methods of total extirpation have undoubtedly greatly reduced the risk of death from the operation itself, and while as long a series as thirty without a death has been reported in one institution, the University Frauenklinik, at Berlin, yet a consideration of the after-history of these patients is strongly in favor of a partial operation.

Taking from Hofmeier's reports, 129 operations of both varieties at this hospital as available for study, because their after-history could be traced, it is found, as stated by Lusk,¹ that at the

end of the first	year, 51	per ct. of the partial	cases remained well.
" second	46	"	"
" third	42	"	"
" fourth	41.3	"	"

¹ American System of Gynecology, ii p. 630.

Again, at the

end of first	year	63.6	per ct. of the complete cases remained well.
" second	"	24.1	" " " " " "
" third	"	26	" " " " " "
" fourth	"	not one living complete case remained.	

So, while brilliant operators, whose death-rate from the operation remains low, may be expected to advocate total extirpation of the uterus, it is likely that the majority of gynæcologists who are more interested in the freedom from recurrence than in the operation mortality, will await the evidence of further experience, now rapidly accumulating, before giving preference to this operation.

When, at the time of discovery, the uterus is found fixed, the vaginal vault infiltrated, and evident involvement of parts which cannot be removed; it is not wise to interfere, unless there be extensive hæmorrhage, extreme pain, or septicæmia from absorption of necrotic material. The same rule holds here as in cancer of the breast; there is an intermediate period, between an early and a late stage, when the highest good of the patient is to be secured by letting well enough alone; correcting fetor by injections of potass. permang., creolin, or hydronaphthol, lessening hæmorrhage by alum or dilute sub-sulphate of iron injections, maintaining the general strength as far as possible by strict attention to the problems of nourishment and good hygiene; securing sleep and comfort by chloral locally or opium by suppository, and waiting. There comes, however, a third stage, when surgical interference may be of great service. When the strength is being rapidly reduced by discharge, by severe hæmorrhage, or by septicæmic fever, the patient should be etherized, and the vegetations rapidly removed by curette or spoon, down to firm, if not sound tissue. A thorough application of the thermo-cautery will then not only arrest hæmorrhage, and lessen the subsequent danger from it, but will check further growth for a considerable time. During the curetting bleeding will be free, but this should be carried on boldly and rapidly until the vegetations have been removed, when it will either cease or be checked by the thermo-cautery. A tampon saturated with some styptic, such as alum, should, however, always be inserted after the operation, and the vagina filled with antiseptic non-absorbent cotton or strips of gauze. This will lessen the risk from sudden hæmorrhage, in the absence of the physician, and should be removed and replaced at proper intervals for several days. It is surprising how much temporary relief will follow for awhile, and existence is often made comfortable for a month or more, while the risk is very small.

For *cleansing purposes* in the general conduct of a case, an experience of a considerable number of cases in the cancer annex of the Home for Incura-

bles, among the out-patients of the University Hospital, and the St. Clement's Dispensary, as well as in private practice, leads to the preference of permanganate of potash solution. It is cheap, non-poisonous, unirritating, and effective. Creolin is now on trial, so far with very satisfactory results.

Hæmorrhage, if not controlled by alum, or other astringent, may often be arrested by pressure so applied by tampon as to bear directly upon surfaces, and not slide over them. If very considerable, it will call for the use of the curette and the hot iron.

For *pain* antipyrin has not proved very satisfactory, though not extensively tried. In one case it gave great relief to general nerve pains, but did not greatly affect the cancer pain. Cocaine is, of course, too transitory and too superficial in action.

Nothing will take the place of opium, guarded by atropia, in the relief of decided pain. Other drugs give much help in insomnia and restlessness when not caused by definite pain from nerve involvement. The opium habit when at length formed, and it may by care be long deferred, is by far the less among evils. No definite improvement in the case, as a whole, has ever seemed to follow the use of drugs given for the disease itself.

A *summary* may be made as follows:

a. Early diagnosis is all-important, and should not be deferred until gross changes have occurred.

b. Examination should follow slight suspicions from the treacherous character of the symptoms. If not conclusive, it should be made by a trained hand.

c. The microscope will sometimes detect before other means will.

d. Heredity is a doubtful cause, traumatic origin very probable.

e. Lacerations of the cervix, where the growths usually begin, should be repaired if causing irritation, and erosions should be cured. If erosions are stubborn, or otherwise suspicious, they should be pared off.

f. In epithelioma especially, the disease is at first local, and if taken early complete immunity is secured sometimes, and always great saving of time and suffering.

g. From an operative point of view, there are three periods in any form of malignant disease.

1. Early, when operation should be immediate and as radical as possible, without extirpation of the uterus.

2. Intermediate when, eradication being impossible, nothing should be done unless demanded by severe hæmorrhage or extreme pain. The length of this period is indefinite, and depends on the rapidity of growth.

3. Late, when scraping and burning may be done repeatedly, to palliate symptoms and retard growth.

DR. W. W. KEEN reported a case of

SIMULTANEOUS AMPUTATION OF BOTH ARMS;
RECOVERY.

For the notes of this case I am indebted to Dr. J. C. Heisler, then surgical interne at St. Mary Hospital, and is put upon record as a contribution, at least, to the statistics of multiple amputations.

Paul K., æt. 15 years, was run over by a street car, at 5 o'clock, P.M., on November 13, 1887. He was admitted to St. Mary's Hospital two hours later. The right hand, forearm and elbow, as well as the left hand and lower part of the forearm, were crushed; both clavicles, also, were fractured.

The boy had lost a great deal of blood before his admission, and was in profound shock when admitted; so grave was his condition that it was doubtful whether he would live through the night.

My colleague, Dr. J. B. Roberts, saw him late in the evening, and ordered whisky and digitalis.

At 10.45 P.M. his temperature was 97°; his pulse 120.

The next morning the temperature was 102.5°; pulse 142. At 1 o'clock P.M. his condition was very grave, but, as he had rallied from the shock, I decided to give him the only chance of his life by amputating both arms. The right arm was amputated below the insertion of the deltoid; the left forearm at its middle. The moment that the first amputation was done, during the dressing of that arm by my assistants the second was proceeded with, so as to lose as little time as possible. He bore the ether badly, and his pulse at times was almost imperceptible. Almost no blood was lost during the operations, the arm being Es-marched above, but not including, the crushed parts. Of course, the most careful antisepsis was carried out. There was no need for hot bottles, etc., as his temperature was well maintained. From the time of the operations his recovery was a perfectly steady one. For the first three days the morning and evening temperatures were about 100° and 102° respectively. From that time on it fluctuated between 99° and 100°, reaching the normal by the tenth day.

On the third day after the operation the anterior flap on the left forearm began to slough; by the end of a week a piece 2 inches transversely by $\frac{1}{2}$ an inch in the axis of the limb was completely separated. The gaping wound now exposed the end of the radius covered with granulations springing from both the periosteum and the medulla. In order to promote adhesion of the flaps extension was applied to them by means of adhesive strips, on which traction was made by a rubber band. This band extended to the end of a straight splint applied to the forearm, counter-extension being maintained also by adhesive plas-

ter which was tacked to the upper end of the splint. At the end of two weeks the lips of the wound were united, and the splint was taken off. The right stump healed kindly, all the sutures being removed by the twelfth day. The boy was up ten days after the operations, and was sent home six days later to come to the hospital as an out-patient until he was entirely well. He was finally discharged at the end of January. Two small circular sequestra separated from the ulna and the radius of the left stump, and were removed January 9th and 24th. The recumbent posture was the only treatment used for the fractured clavicles. They united very well, and with but little deformity.

DR. E. P. BERNARDY reported a case of

UNIQUE PRESENTATION OF A FŒTUS.

The patient who gave birth to this child was a primipara, æt. 18 years. I saw the case for the first time at 8 o'clock, April 8, 1889; the membranes had been ruptured four hours, the fœtus was presenting in the right oblique diameter; the presenting part seemed to be the breech, the right side deeper in the pelvic cavity than the left; the fingers could be hooked in what appeared the groin, but did not have the full feeling one would expect in breech. A sort of sulcus or fissure was in the centre of the presenting part. Passing the fingers further upward, the bone of the skull was detected. I thought that I had a double pregnancy, the breech of one presenting, and the head of the other imbedded in the chest of the first. External palpation showed the uterus divided in two by a deep dent in its fundus, a large body occupying the upper left portion, and a body occupying the lower portion of the right side.

I did not introduce my hand into the vagina, for the maternal parts (vulva) were rigid, and had not undergone any softening, and such examination would have undoubtedly caused a rupture of the perineum; the os was spasmodically contracted around the presenting part. The patient not having much pain, and having to deliver a hydrocephalic case, I left her for about two hours. On my return, the entire portion which you here see, was grasped by the vulva, and the child was delivered in this position. It will be seen that both shoulders presented fair and square, the neck, somewhat stretched, thrown forward on the chest, and the head, slightly twisted sideways, laying in a cavity in the chest; the arms laid on the top of the chest, right and left side, the head between. There was hardly any pain connected with the confinement.

This is a rare case; I cannot recall an instance of a similar presentation.

(To be concluded.)

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR REGULAR CORRESPONDENT.)

Proposed Hospital for the Study and Curative Treatment of Insanity—Compressed Gas for the Removal of Warts—Experiments with Massage—The Medical Aspects of Life Insurance—Hysteria in the Male Identical with the Disease as seen in Women.

On the motion of Mr. Brudenell Carter the London County Council has appointed a committee "to inquire into and report to the Council upon the advantages which might be expected from the establishment, as a complement to the existing asylum system, of a hospital, with a visiting medical staff, for the study and curative treatment of insanity." The report of the committee will be awaited with much interest by all who devote attention to this most painful subject. It is thought that the authorities of the existing asylums are so much engaged in administrative work that they have little time for scientific study. In the proposed hospital, the primary duty of the visiting medical staff will be to investigate the conditions of insanity and to discover, if possible, more effectual remedies than any that have yet been found for one of the most grievous of human maladies. It is to be hoped that the suggestion as to a hospital will receive most thorough consideration, and that the committee will take care to obtain the very best advice that can be offered by the medical profession.

Dr. Benjamin W. Richardson, ever foremost in practical scientific medicine, has made a suggestion which is as interesting as it is novel. It is to use a jet of highly compressed gas as a cautery. It is known that accidents occur to workmen sometimes in factories where compressed gases are prepared or employed by such a jet impinging on any part of the body, and causing an injury of the same nature as a burn. Dr. Richardson turns this property to account, and suggests its employment for the removal of warts and small pendulous growths. It does not appear that he has carried out the idea in practice, but he intends shortly to do so. He points out its advantages over the cautery, heated wire or knife, in that it is less alarming and for the moment painless, as cold is an anæsthetic. He enumerates the gases which might be used and specifies chlorine as no doubt most effective. He, however, gives the palm to carbonic anhydride (CO_2) as most manageable, cheap, almost inodorous, not unwholesome and not inflammable, so that it can be used with artificial light. It is now a little over twenty years since Dr. Richardson introduced ether spray as a means of producing local anæsthesia. It remains to be seen whether the present suggestion

may not lead to an equally important weapon in the armory of the surgeon.

A medical man has kept four students under observation while they underwent a daily course of massage for twenty minutes. All four methods, viz.: effleurage, pétrissage, friction and tapotement, were brought into play at each operation. The general result was that in every case the appetite showed considerable improvement, not merely during the week in which massage was performed, but during the week following as well. Two of the patients increased in weight in the course of the week's massage, while two decreased; but, curiously enough, all showed a marked increase during the subsequent week. In every instance it was observed that the respiration became fuller and more frequent, while the beating of the pulse increased in rapidity when effleurage was in progress, decreasing when pétrissage was substituted.

For four nights Dr. E. Symes Thompson, the Gresham Professor of Medicine, interested as many people as the theatre of Gresham College would hold while he lectured to them on "The Medical Aspects of Life Assurance." Speaking on the insurance of young infants, the doctor said that certain offices existed which insured very small babies in such a manner that a very great temptation was put upon the guardians or parents of the children to hasten them out of the world. It was curious to note that in the places where mortality among infants was exceptionally high, the desire of parents to insure their children was very pronounced. As showing the enormous advantage that the totaller has of living long as compared with the general body of mankind, the doctor exhibited two statistical tables—one of the Rechabites and the other of the Oddfellows, from which it appeared that among the Rechabites the average sickness per annum was four days, the death-rate was one in 141, and the weekly payments were 5s. 9½d., while among the Oddfellows the average sickness was thirteen days, the deaths averaged one in 44, and the weekly payments amounted to 13s. 1d. What made the contrast more remarkable was the fact that the Rechabites admitted females as members, while the Oddfellows would have nothing to do with the ladies.

Dr. Adami considers that, for all practical purposes, hysteria in the male is identical in its manifestations with the disease as seen in women. He divides the cases into two classes, the first including those cases which were complicated by the occurrence of the so-called hystero-epileptic attacks, though, as suggested by Sir William Roberts, hysteroid attacks would be a better term. The second group consists of those attacked by hysterical hemiplegia or paraplegia. The male hysteric was rarely so emotional as the female; most often he is rather phlegmatic than emotional, and in him the attack of "grand hys-

teria" rarely or almost never, even in France, passed on to that series of exaggerated portrayals of emotions which Charcot had described as occurring in the most advanced female hysteroid-epileptics. The most usual period for hysteroid fits in the male is from 18 to 22. In the second class of male hysterics there might occur almost every variety of mono- or hemi-paraplegia, aphonia was frequent, though the face was not affected. There might be contractures, with diminished or increased tendon reflexes, various forms of anæsthesia and hyperæsthesia, and vaso-motor disturbances with affection of the muscular sense and the special senses, notably retraction of the field of vision. Such cases most frequently resulted from injury, notably railway accidents, though not a few, as in women, were apparently related to disturbances of the generative function.

Dr. Horatio Donkin has married the widow of Professor E. H. Palmer, the distinguished Orientalist and traveler. Dr. Donkin, it may be remembered, was Professor Ray Lankester's principal assistant in the exposure in 1876 of Dr. Slade, the Spiritualist.

Medical men in general are probably not aware that in France, at least, the doctor's claim on the estate of a deceased patient has precedence of all others. Even the landlord's claim for arrears of rent must yield to the doctor's fee. The courts have recently decided that, as it is an imperative right of humanity that the dying should have the necessary care and treatment, such attendance should be paid for before all the other debts.

A £10,000 fee has, it is stated, been given to Dr. Freyer, a surgeon in India, for his successful treatment of the Nawab of Rampur.

Trichina in muscle can be detected, it is stated, by placing thin slices of the suspected meat in a test tube with pepsin, water, and a little hydrochloric acid. After a few hours' digestion in a warm place, the parasite will become so loose and prominent that it can be easily picked out with a needle and identified under the microscope.

An obituary announcement in a daily paper recently included the remark that E. P. wishes to express his thanks to the Superintendent of the hospital and the many doctors who attended him during his last illness.

G. O. M.

DOMESTIC CORRESPONDENCE.

shall the Section of Obstetrics and Diseases of Women be Abolished?

Dear Sir:—At the last meeting of the Association a member introduced an amendment to the By-Laws looking to the abolition of the Section of Obstetrics and Diseases of Women; relegating

the former branch to the Section of Pediatrics, and the latter to the Section of Surgery. Inasmuch as the proposed amendment will be acted upon at the approaching meeting at Newport it should receive very careful consideration, and particularly since it involves a radical change in the working organization of the Association. That such consideration may be had I beg to direct attention to a few facts bearing upon the action contemplated by the amendment indicated.

The Section of Obstetrics and Diseases of Women has for a number of years been one of the most largely attended and most active of the various Sections of the Association. The papers annually presented there come from all parts of the Union, by men eminent in these departments of medical science, and a large number of practitioners annually attend and participate in the discussions. The programme of this Section, as published for the approaching meeting, is the largest in number of papers and most comprehensive in the range of subjects of any of the Sections, embracing forty-eight (48) papers, many of the authors being of National, and some of worldwide reputation. Hence it cannot be justly claimed that the Section as now organized is wanting in efficiency. Let us then consider some facts bearing upon the relation of obstetrics and gynecology, which naturally associate these two departments scientifically and practically, and which, at the same time, show that the separation would necessarily impair the cultivation of both by the members of the American Medical Association.

The intimate relation and connection of these two branches has long been recognized in our system of teaching, both in this country and in Europe; in practice, in medical literature, and in the organization of societies, local and national. In most medical schools in America and Europe the two branches are taught jointly. *The American Journal of Obstetrics* and *The Annals of Gynecology* are devoted to the joint cultivation of these associated departments of medical science and practice. The American Gynecological Society, and that energetic organization recently instituted, the American Association of Obstetricians and Gynecologists, not to mention the Obstetrical Societies of Philadelphia, of New York, of London, and other cities attest the same fact.

Not only are these branches united in our system of education, in our literature, and in our society organizations, but in practice. One of the most distinguished of American laparotomists is the Physician-in-Charge of a model maternity hospital, and almost all American gynecologists are connected with public obstetrical services. In many of the most admirable European institutions the obstetrical and gynecological departments are under the same roof and conducted by the same

head.¹ In private practice most of the leading gynecologists are habitually engaged in obstetric practice as attendants and consultants.

But there are weightier reasons still why this important Section of the Association should not be divided. The greatest triumphs of modern obstetric science and the most important improvements in obstetric practice consist in the application of the principles of abdominal surgery to the lying-in woman. The technique of modern obstetric practice and that of pelvic surgery are formulated upon the same principles and require the same line of study and training for their mastery. The woman after labor is exposed to the same great danger of sepsis as the woman after ovariotomy. To execute the improved Cæsarean section requires all the skill and knowledge essential for the most difficult intra-abdominal operation and a thorough familiarity with pregnancy and the puerperal state.

Most of the operations in gynecology are for conditions the result of, and directly connected with, pregnancy and parturition, and of necessity involve thorough knowledge of those conditions.

For these reasons both the study and practice of obstetrics and gynecology must remain so correlated that they can only be successfully cultivated conjointly. To abolish this Section of the Association, now so successfully conducted, would scatter the members into other crowded Sections, and do the cause of science and the Association serious injury.

* * *

MISCELLANY.

THE CRONIN ASSASSINATION.—The Chicago Medical Society adopted the following resolution at a meeting at the Grand Pacific Hotel June 3d:

WHEREAS, Dr. P. H. Cronin was recently decoyed from his office and assassinated; and

WHEREAS, Dr. Cronin, although not a member of the Society, was a regular member of the profession, of recognized ability;

Resolved, That the death of Dr. Cronin, occurring as it did, while the Doctor was in the intent of extending to a sufferer the benefices of our art, is a matter of deep regret to the members of the Society; and

Resolved, That the Secretary be instructed to extend to the relatives and immediate friends of the deceased the sympathy of the fellows of this body.

THE 75,000 EXTRA EDITION.—The "Extra Edition" of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION has come to us full of interest and information. In a special article by Dr. Wm. G. Eggleston, of Chicago, it gives a tabulated list of the various medical colleges in the United States, their date of organization, matriculation and graduation requirements, etc., and adds facts which deserve the notice and careful consideration not only of practitioners, but students of medicine, and those contemplating entering this field of professional life. Much is being said upon the subject herein treated, the

laudable intent of which is to elevate the standard of medical education throughout our country, and we add our voice to the movement, hoping that some steps may be adopted which may at once check the increasing tendency of many little competent and poorly prepared to undertake a work of so great importance and responsibility as the practice of medicine, and aid our colleges, while denying none worthy, in sending out only graduates well equipped for the sacred duties of physicians.

THE JOURNAL announces the annual meeting of the American Medical Association to be held at Newport, R. I., June 25, 26, 27 and 28, giving a programme of the same, and adds attractive views illustrating this beautiful city by the sea. We join in wishing that the convention may be as pleasant and profitable as those of the past.—*The Atlanta Medical and Surgical Journal*.

POSTPONEMENT.—The Annual Meeting of the Pennsylvania State Medical Society has been postponed until the first Tuesday in September in consequence of the recent disastrous flood in the Conemaugh Valley.

THE MCLEAN COUNTY (ILL.) MEDICAL SOCIETY.—This Society met in regular session at the office of Drs. Darrah & Corley June 3d. There were present, Drs. H. Parkhurst, T. W. Keys, G. R. Smith, H. A. Winter, F. J. Parkhurst, N. F. Jordan, J. B. Taylor, A. T. Darrah, W. A. Elder, L. E. Spear, C. J. Corley, F. J. Welch, W. H. Reedy, W. L. Pollock, C. C. Sater, H. F. Ballard. The session was devoted to a discussion of the physiological action of antifebrin and antipyrin. The discussion was general and very interesting. It was conceded by all that these new remedies were not only useful as antipyretics, but were of much value in a variety of diseases, especially those of a rheumatic and neuralgic character. The fact was developed that the remedies under consideration were powerful sedatives and required great caution in their use. Dr. Rhoda Galloway, a graduate of the Woman's Medical College, Chicago, was elected to membership. Dr. J. B. Taylor extended an invitation to the Society to attend the commencement exercises of the Wesleyan University, June 13, to hear the address of Dr. M. L. Fullinwider, of Eldorado, Kan. The invitation was accepted, and the Society voted to attend as a body. The application of Dr. H. F. Ballard, of Chenoa, for membership, was received and referred to the Board of Censors. The President appointed Drs. J. B. Taylor and C. J. Corley as essayists for the September meeting, and the Society adjourned to meet the first Monday in September.

THE meeting of the Mitchell (Ind.) District Medical Society will be postponed till July 18, 19 and 20th, at West Baden, Ind., on account of the meeting of the American Medical Association.

IN the Bombay Presidency no fewer than 1,168 human beings were destroyed by snakes during 1887, and over 300,000 venomous snakes were destroyed.

THE ODOR OF SOUND MEAT.—In the normal state the flesh of every animal has its own characteristic odor. Beef has a special insipid kind of smell, modified by the different modes in which the animals have been fed. Thus it is stated that the flesh and milk of cattle in the polar regions has a fishy odor, because the absence of pasturage obliges the inhabitants to feed their oxen and cows on fish. Veal smells of milk, mutton of wool and sometimes grease. The normal odor of pork is insipid and inoffensive, but when the pigs are fed on offal the flesh has a pale cachectic hue, and an offensive smell and taste. The odor of poultry fed on corn differs from that of poultry artificially fattened. In a diseased state, meat emits a typical odor resembling the breath of feverish patients. This odor is particularly noticeable beneath the shoulder, and in the muscles of the inner side of the leg. The odor should be carefully noted immediately

¹ For example, the admirable Frauenklinik conducted by Professor Freund, in Strassburg, and that by Professor Winckel, in Munich.

after the incision is made. This should be done by the inspector himself. When diseased meat is roasted it emits a strong and offensive smell. The fever odor is particularly marked in the case of animals which have suffered from peritonitis, charbon, morbid symptoms following parturition, or with ordinary acute disease. In such cases the smell is recognizable at once, and it is unnecessary to make any incision. "Feverish" meat is always unfit for consumption.—*The Annals of Hygiene.*

THE MERCURY SALTS are among the most important of the substances affected by actinic light. The conversion of the *mercurous*, or non-poisonous, to the *mercuric*, or poisonous salts, is likely to be attended with fatal results, when the change has been sufficiently great. Calomel, therefore, should be kept in amber bottles away from light to prevent its being converted into the poisonous corrosive chloride.

DEATH OF WARREN DE LA RUE.—*The National Druggist* says: This man, noted alike as an astronomer, chemist, electrician, physicist, photographer, and pharmacist, and as an investigator and writer in almost all domains of scientific research, died at his home in Guernsey, April 19, aged 74 years. In his early years he succeeded his father as the head of the Paris manufacturing house of Thos. de la Rue & Co., and continued in this position until 1880, when he retired. His published works embrace almost the entire domain of science. In pharmacy his greatest, or at least best known, were his investigations of cochineal and (in conjunction with Müller) of rhubarb and its constituents, and to him, with Müller, belongs the discovery and isolation of chrysophanic acid. The notice of his death in the *Pharmaceutical Journal and Transactions* says: "But his name is most associated with the application of photography to the recording of celestial phenomena, on which subject he produced a large number of papers. In connection with Dr. Müller, also, he carried on a series of investigations upon the electrical discharge, using a battery of 15,000 chloride of silver cells, the results of which were given in a collected form in a lecture at the Royal Institution in 1881. Amongst the many honorary posts filled by Mr. de la Rue may be mentioned those as honorary Secretary, and afterwards President of the Astronomical Society, President of the Chemical Society for two separate periods, President of the London Institution, and Secretary of the Royal Institution. In addition he was a member of numerous foreign learned societies.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from May 25, 1889, to May 31, 1889.

By direction of the Secretary of War, Major John S. Billings, Surgeon, is authorized to make, in connection with his duties as supervisor of mortality and vital statistics of the eleventh census, such journeys as may be ordered by the superintendent of the census, provided that, in each case, the approval of the Surgeon-General shall be obtained; and provided further, that the journeys shall involve no charge against the fund for transportation of the Army. Par. 12, S. O. 122, A. G. O., May 27, 1889.

Major Henry McEldeery, Surgeon U. S. A., is granted leave of absence for one month, to take effect upon completion of his duties as a member of the Army Medical Examining Board in New York City. Par. 4, S. O. 117, Hdqrs. Div. of the Atlantic, Governor's Island, New York City, May 23, 1889.

Major J. H. Patzki, Surgeon, is granted leave of absence for twenty-one days. Par. 1, S. O. 44, Hdqrs. Dept. of Ariz., Los Angeles, Cal., May 18, 1889.

Capt. Paul R. Brown, Asst. Surgeon, is granted leave of absence for six months on account of sickness, by direction of the Secretary of War. Par. 13, S. O. 122, A. G. O., May 27, 1889.

Capt. Walter W. R. Fisher, Asst. Surgeon, leave of absence for one month granted by S. O. 30, c. s., Dept. of California, is extended fifteen days. Par. 3, S. O. 37, Hdqrs. Div. of the Pacific, San Francisco, Cal., May 22, 1889.

First Lieut. Ogden Rafferty, Asst. Surgeon U. S. Army, ordered with troops for field practice to Galveston, Texas, where troops will camp for such time as may be hereafter directed. Par. 1, S. O. 29, Hdqrs. Dept. of Texas, San Antonio, Tex., May 13, 1889.

By direction of the acting Secretary of War, First Lieut. James D. Glennan, Asst. Surgeon, is relieved from duty at Willett's Point, N. Y., to take effect June 1, 1889, and will proceed to Ft. Riley, Kan. Par. 5, S. O. 121, A. G. O., May 5, 1889.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending May 25, 1889.

Surgeon W. H. H. Hutton, to proceed to New Orleans, La., and inspect unserviceable property. May 25, 1889.

Surgeon George Purviance, detailed as chairman Board of Examiners. May 22, 1889.

Surgeon H. W. Austin, detailed as member Board of Examiners. May 22, 1889.

Surgeon John Godfrey, detailed as recorder, Board of Examiners. May 22, 1889.

P. A. Surgeon John Guitéras, resignation accepted, by direction of the President, as tendered, to take effect April 30, 1889. May 11, 1889.

P. A. Surgeon S. T. Armstrong, granted leave of absence for thirty days. May 11, 1889.

THE COMPARATIVE RESULTS OF LITHOTOMY, LITHOLAPAXY AND LITHOTRITY IN ONE HUNDRED OPERATIONS FOR STONE.

BY EDMUND ANDREWS, M.D., LL.D.,

PROFESSOR OF CLINICAL SURGERY IN CHICAGO MEDICAL COLLEGE,
AND SENIOR SURGEON OF MERCY HOSPITAL.

The new instruments and modified methods introduced by Bigelow, of Boston, for crushing and evacuating vesical calculi seemed at first dangerously severe. In litholapaxy one must often work with his instruments in the bladder for more than an hour, and it naturally impressed surgeons as a rash and perilous procedure. I confess to having felt strong fears in this direction, and many other surgeons were even more timid in the matter than myself. Prof. Paul F. Eve seems to have avoided the new plan almost entirely, and Prof. James R. Wood, of New York, shortly before his death, showed me his collection of vesical calculi, and informed me that he had just cut for stone the ninetieth time, and had never crushed in a single instance.

However, experience soon showed that the bladder is far more tolerant of even a whole hour or more of careful instrumentation, which thoroughly clears it of debris, than of incision, or of repeated brief crushings which leave a mass of sharp-angled fragments in the cavity for days together. In short, the danger of litholapaxy has proved, in my practice, decidedly less than that of the old style of lithotrity, or of lithotomy. All hesitation has vanished. I have now operated for stone one hundred times; fifty-five times by cutting, with seven deaths; six times by the old style of lithotrity of Civiale and of Sir Henry Thompson, with one death; and forty times by Bigelow's litholapaxy, with one death. The following is a summary of the cases:

SUMMARY.

Total number of cases of lithotomy, 55; deaths, 7; mortality 13 per cent.

Lithotomy below age of puberty, cases, 26; deaths, 2; mortality 8 per cent.

Lithotomy above age of puberty, cases, 29; deaths, 5; mortality 17 per cent.

Lithotrity after the manner of Sir Henry Thompson, cases, 6; deaths, 1; mortality 17 per cent.

Litholapaxy after the manner of Prof. Bigelow, cases, 40; deaths, 1; mortality 2.5 per cent.

Of the 101 operations above tabulated, two only were upon females.

It will be observed that the total number of operations in the tables is 101, instead of 100. This is in consequence of including one litholapaxy in addition to those performed with my own hands, which was done on a hospital patient by my colleague in my temporary absence.

The increase of safety by the introduction of litholapaxy is immense, and, in my opinion, almost all adult operations for stone in the bladder should be done by this method. However, let no man delude himself with the notion that this rule has no exceptions. The following classes of cases still require the cutting operation:

1. All children whose urethra are too small to admit small-sized lithotrites.

2. All cases where the stone is too large to be grasped by the instrument. Case 14,714 was of this character. Having a diameter of 9 centimetres, the jaws of the instrument could not grasp it, and I was obliged to proceed by suprapubic lithotomy. The peculiarities of this case give it special interest. It turned out that there was a thick mass of connective tissue indurated by inflammation between the bladder and the upper border of the pubis. I first introduced into the bladder the French instrument called the *sonde à dard*, in order to use it as a guide to the suprapubic incision. It is made like a strong silver catheter, but carries in its canal a curved steel dart or stiletto with a groove on its surface. The operator inserts it into the bladder and, pressing the tip against the front of the viscus, pushes the dart forward till it pierces the tissues and appears in the bottom of the primary incision. The bistoury is then entered into the groove and guided by it into the bladder. In this case the dart would not pierce the tough mass of tissue, and I was obliged to go in with the scalpel alone. I finally found the cavity with the stone in it, well back against the rectum, after a dissection of alarming depth, and then extracted the immense calculus without further difficulty.

3. In a few cases mulberry calculi are so hard

that they cannot be crushed without breaking the lithotrite. Case 13,605 was of this sort. Seizing it, I was unable to break it with the utmost strength of both hands applied to a strong lithotrite. Calling an assistant to take hold with me we commenced to exert our full force, when a metallic clink from within the bladder told that the instrument was broken. The shank of the female blade was cracked half across, and distorted enough to prevent closing the jaws again. Here was a dilemma. The instrument could not

be drawn out unless closed, and for a time it was probable that it would be necessary to incise freely upward through the perineum, pry the open jaws of the instrument downward through the incision, and file off the shank. However, I succeeded after a time in slipping the blades past the hitch, and closing the jaws. I then withdrew the lithotrite and proceeded at once to remove the stone by lateral lithotomy. The patient recovered, but it was proved that two strong men are too much for one lithotrite. I think it probable,

LITHOLAPAXY, OR EVACUATION OF STONE AT ONE SITTING

* Record lost.

also, that a stone might sometimes be found accreted around some smooth piece of steel or iron previously slipped into the urethra by the patient and lost in the bladder. The calculous mass could easily be crushed loose from the steel, but unless the surgeon could succeed in seizing the latter by the end, he could not withdraw it, and might possibly have to cut for it. Two or three times I have found stones containing rolls of chewing gum for nuclei. The gum is slightly pasty, but it breaks into pieces small enough to come readily out through the tubes. I judge that we ought to have a lithotrite a little thicker and stronger than any now made to apply to unusually hard stones.

4. Deformities of the bladder sometimes render it impossible to seize a stone. The deformity may consist of a sacculus too deep to be explored by the jaws, or a stone may be hid behind a prominence of the prostate, so that a lithotrite cannot reach it. I was once called in council by a skilful surgeon who, in attempting lithotomy, found this difficulty to such an extent that, though he had already cut the patient, he could not seize the stone with his lithotomy forceps, because they happened to be straight. My own forceps, which are curved, seized it without much difficulty.

5. Strictures of the urethra forbid litholapaxy, unless they are first overcome. Case 14,841 had this obstruction. It was first divided by Maisonneuve's stricture cutter, and the litholapaxy successfully performed about a week later.

These various obstacles to litholapaxy are rarely insuperable in adults, so that out of forty-two proposed operations of this sort, only two had to be changed to lithotomy; yet these two are enough to show that a surgeon should always go to a case prepared for either operation.

Case 8,497 (lithotomy) was remarkable for containing nine stones, of which six were of large size and accurately fitted to each other by attrition, as shown in the annexed cut. Their combined weight was 176 grams.

Prof. Bigelow's main improvements are thoroughly established, at least until something better can be devised; yet, excellent as it is, litholapaxy in its present form has certain objectionable features which are common to all efforts to evacuate the crushed fragments by a to and fro current. The bulb of his apparatus is first compressed, driving some water into the bladder, and then allowed to expand and draw it out again. This expansion draws a stream of fragments with

it, some of which reach the bulb; but, as the suction lasts only during the instant of the bulb's expansion, the current ceases and stops a long row of fragments in the tube, only to drive them swiftly back into the bladder at the next compression. By this churning to and fro many sharp-angled pieces are alternately drawn out of the bladder and shot back into it scores of times before they finally escape into the bulb, thus irritating the bladder by the pelting of sharp fragments, and by the constant and prolonged repetition of forced distensions.

Figure 1.

Evidently we need, not a churning to and fro, but a continuous current, always in one direction, but, as the outflow tube must be large, to allow the pieces to pass it, one would judge at first thought that there would be no room for a sufficient inflow tube by the side of it.

Careful mathematical calculations, verified by experiments, showed me three years ago that, by having a reservoir of warm carbolated water 42 inches above the pubis of the patient, and a peculiarly constructed double tube, the inflow channel can be reduced to a small size, and still supply a current forcible enough to sweep all fragments rapidly out of the bladder. The following cuts illustrate the apparatus:

Figure 2

Figure 3.

Fig. 2 represents a bucket or other reservoir filled with warm carbolated water and suspended 42 inches above the patient's pubis, while a syphon of rubber tubing descends from the bucket to the inflow branch of the evacuating tube.

A strainer shaped as in Fig. 3 is attached to the upper end of the tube and dropped into the bucket. The evacuating tube is double, and the inflow part is smaller than the outflow, and lapped halfway around it as shown in enlarged cross sections in Fig. 4, where the cylindrical tube A B is the outflow channel and the lunate space B C is the inflow portion.

Fig. 5 gives a side view of the evacuator. Z is the inflow tube which attaches to the rubber syphon shown in Fig. 2. The inflow tube passes by the curved outflow tube J O without infringing on its calibre, and laps itself around the under half of the outflow tube as shown at B C, Fig. 4. Near the end X, it discharges into the bladder by about thirty small openings. This sends a copious current into the bladder, which rushes into the fenestrum X of the outflow tube X J O., and sweeps out the crushed fragments with great velocity.

It will be observed that the outflow pipe is prolonged a little by a piece of rubber tubing, J O, the use of which requires a word of explanation. Both in Bigelow's instrument and in my own, the fenestrum X is often blocked by several fragments rushing to the orifice at once and locking themselves together in a sort of arch, obstructing the outflow and causing a sudden diminution of the stream of water. When this occurs the surgeon closes the lower end of the short rubber tube J O

Figure 4.

Figure 5.

by seizing it with the thumb and finger of one hand, and then with the corresponding digits of the other hand suddenly compresses the rubber

just above. This sends a quick, forcible jet back into the bladder, driving back the fragments lodged across the fenestrum X, and permitting the outward current to resume its course. I devised this apparatus three years ago, and have reason to be highly pleased with its use.

In respect to the new term, litholapaxy, some object that it designates only an improved form of lithotripsy, and consequently that Bigelow is not really entitled to inflict it upon an art already overburdened with technicalities, and some European authors decline to use it. However, there are good reasons for adopting it. Lithotripsy is a harsh, rough word, and has the inconvenience of sounding so much like lithotomy when carelessly spoken, that surgical teachers and pupils dislike it. Litholapaxy, on the contrary, is smooth and easily distinguished. Moreover, it etymologically means "stone evacuation," and hence is appropriate to include both cases of actual crushing, and also those frequent ones in which the great tubes of Bigelow evacuate stones of some little size without the necessity of crushing. The ability to do this is an important merit. It is probable, therefore, that the word litholapaxy will remain in use, and lithotripsy disappear.

No. 6 Sixteenth St., Chicago.

FOUR CASES OF GUNSHOT WOUND OF THE ABDOMEN TREATED BY LAP-AROTOMY, WITH REMARKS.

Read before the Kentucky State Medical Society, May 9, 1889.

BY DAVID BARROW, M.D.,
OF LEXINGTON, KY.

Case 1.—On July 28th last, about midday, I was requested to see a man at St. Joseph's Hospital, who was reported to be shot in the abdomen. Finding him in the ward, we obtained the following history, principally given by others, though he himself was conscious and would answer questions.

M. K., white, aged 31 years, strong and muscular, had that morning, at Payne's Depot, a station eight miles from Lexington, been shot. He was brought to Lexington on the train, and from the depot to the hospital in a wagon. He had vomited frequently, and had suffered continuous and intense abdominal pain; so great at times that morphine was given hypodermically. Thirst was intense, and considerable water was drunk, with the effect, usually, of causing him to vomit, and so great was the collapse at times that during the rough journey stimulants were given.

He was shot with a 44 Colt's pistol at 10 A.M., and we saw him two and a half hours later. His condition at our visit was one of marked shock. He lay upon a bed breathing rapidly, and wet with perspiration. The movements of the upper

extremities were frequent and restless, and the thighs were flexed slightly upon the abdomen; the pulse was rapid, weak and irregular, expression anxious and skin cold; vomiting frequent, and he complained bitterly of pain in the abdomen. The wound was $1\frac{1}{2}$ inch to the left of and $1\frac{1}{2}$ inch below the umbilicus; the ball had passed through the rectus muscle, and from the wound projected a portion of the omentum, somewhat soiled and injected, but not strangulated; the abdomen was hard and retracted, and dull over most of its anterior region, and from the wound came every few seconds blood and gas, the odor being faecal. By firm pressure a considerable quantity of blood could be forced out of the cavity. His condition, with this evidence and the location of the wound, made it certain that the alimentary canal was wounded, and possibly other important structures; also, an active hæmorrhage was going on. There was only the wound of entrance, and this gave no evidence of the course taken by the ball.

An operation was decided upon, and a physician who had, unfortunately, been a party to the shooting, and who was present, urged that it be done at once; so, the patient's consent being obtained, everything was made ready.

Antisepsis was attempted, using for instruments carbolic acid, and for all other purposes bichloride of mercury. He was put upon the table three and a half hours after being shot, and the anæsthesia begun. There were present Drs. Brock, Coleman, Molloy and Robinson, and they kindly assisted me in the operation. The integument, after being carefully washed with water and soap, was shaved and washed with ether, and wet bichloride towels were applied. The incision was in the median line, between the umbilicus and pubis, and about 4 inches long. Dissecting carefully until the peritoneum was reached, it was incised between forceps, and the cut enlarged with the finger as guide in the peritoneal cavity. Blood welled up, and considerable gas escaped. As hæmorrhage continued free, the intestines, after the incision was enlarged to about 7 inches, were rapidly delivered and surrounded with warm bichloride towels, and the bleeding vessels sought.

Two branches of the superior mesenteric artery were found bleeding—these were controlled by forceps and left to be tied later. The intestines were then carefully examined, and seven large, ragged perforations found. The mesentery was also wounded in five places and badly lacerated. The intestines were empty, and there was no faecal extravasation.

The perforations being very ragged, were trimmed with the scissors and closed with the continuous Czerny-Lembert suture, using fine catgut for the purpose. After suturing the perforations, the mesenteric vessels were ligated and all raw surfaces of the mesentery approximated. The intes-

tines were then, after being cleansed, returned to the cavity.

During the entire suturing warm bichloride towels, 1 to 20,000, protected the intestines, and as little manipulation was done as possible under the circumstances. The cavity was thoroughly irrigated with several pitchersful of bichloride solution, and sponged clean and dry. The incision was closed with silk and no drainage tube put in; antiseptic dressings were applied and the patient put in a warm bed. The duration of the operation was two hours, and most of the time the pulse could not be counted. Stimulating hypodermics were given, and he was kept surrounded with hot bottles and given hot water enemata. He rallied after awhile and spoke with his sister, and the heart's action improved, but soon he became restless, and died three hours after being put to bed. During the anæsthesia both chloroform and ether were given.

Remarks.—In this patient collapse was the most prominent condition, partly due to the rough trip, but mainly to the loss of blood. The transfusion of a saline solution might have improved his condition. In operating the first thing to do was to check hæmorrhage, and with that in view, the intestines were rapidly delivered and the bleeding vessels caught; after which the injuries were repaired, this being a long and tedious process, as the perforations were large and ragged. In suturing, I commenced about $\frac{1}{4}$ inch from the margin of the wound, and after taking the first stitch, tied the thread, leaving the free end about 6 inches long; then continuing with the suture beyond the opposite margin of the wound, and returning with the Lembert suture to the point of starting, and there tying with the free end. In this way each perforation was rapidly and doubly sutured and the thread tied securely. A drainage tube should have been used, but having none at hand, and hurrying to get the patient off the table, I closed the incision, but with the intention of introducing one later, should there be any indication for so doing. The bullet passed from left to right, and downward and backward. The hæmorrhage, I feel sure, was the main cause of this patient dying so soon; the length of the operation with its consequent manipulation and exposure, and the long anæsthesia were, of course, additional factors in hastening death.

Case 2.—D. J., white, æt. 25, strong and muscular, was first seen in a saloon at 10 P.M., November 6, where he had been shot with a .38 calibre pistol about a half-hour before; he was drunk, and had been since early morning, and had eaten nothing. After being shot he was laid upon a box in the back part of the room, where he was when I went in. The wound was one inch below and three posterior to the left ant. sup. spine of the ilium, and just below the liver and under the skin, and three and a half inches

to the right of the median line the bullet could be distinctly felt.

He was shot while leaning upon the counter, and the ball had traversed the abdominal cavity from below, upward, and from the left to the right side. His pulse at this time was less than 100, strong and regular; no vomiting had occurred, nor was there much evidence of shock; he was restless and talkative, and complained of abdominal pain, and begged that I should give him relief. A third of a grain of morphine was injected, and his friends were instructed to carry him home, which was about a mile off, which they did, after placing him on a mattress in a wagon. I returned to the office for assistants and instruments. Drs. Coleman and Molloy accompanied me to his house and there we found him resting quietly and under the influence of the morphine, apparently no worse from the ride in the wagon.

The wound was again examined, and by enlarging it slightly I succeeded in following the track of the ball through the ilium and demonstrating that the abdominal cavity had been entered. After consultation, laparotomy was agreed upon, but owing to the unfavorable surroundings at his home it was thought best to have him taken to the hospital. He was therefore again put into the wagon and taken to the hospital, reaching there about 1 o'clock in the morning.

At this time there was more evidence of shock, the pulse was 120, and much weaker; he had vomited several times, and his expression had become anxious and his movements restless, and he complained more of abdominal pain.

Chloroform was administered, and at 2 o'clock, by gas and lamplight, I began the operation. Hands and instruments were scrubbed in carbolyzed water, and the patient's abdomen thoroughly cleansed and shaved. The incision extended from a little below the ensiform cartilage to near the umbilicus, and on incising the peritoneum considerable gas and blood escaped; the intestines presented at the opening and it required great care to prevent their being forced out upon the abdomen. The cavity contained about a quart of bloody fluid, but no fecal matter was seen. The small intestines were first examined, and nine perforations found; other viscera liable to injury were seen as best I could through the incision, but no wounds were found, save those of the small intestines and several of the mesentery. A branch of the superior mesenteric artery was found bleeding and it was tied with fine silk. Six of the perforations were sutured, as in the previous case, using very fine carbolyzed silk; the other three being close and destroying a large part of the bowel lumen were resected, about $\frac{1}{4}$ inches of the gut being cut out, and with it a triangular piece of the mesentery. The resected ends were united with the Czerny-Lembert suture and the cut surfaces of the mesentery were carefully ad-

justed and sewed; two small vessels were divided and tied with fine silk. The intestines were protected during the operation with warm wet towels, and were manipulated as little as possible. The peritoneal cavity was then sponged out, and after considerable manipulation and many futile attempts at replacement the incision was enlarged to 7 inches, and then only after puncturing the canal and evacuating the gas, did I succeed in returning the intestines to the cavity, at least a half hour being spent in this effort.

In closing the incision several relaxing sutures were used before the edges could be coapted, and during the entire time great difficulty was experienced in retaining the intestines in the abdominal cavity. The wound through the ilium was left open. The bullet was removed through an incision over it. The operation lasted two hours, and towards the end the patient became collapsed, and stimulating hypodermics were freely given. Antiseptic dressings were applied and he rallied fairly well after being put to bed and surrounded with hot bottles. About an hour afterwards he became delirious and force was necessary in preventing his getting up; so violent was he that morphine was injected.

At my first visit, five hours after the operation, he was resting quietly, with favorable symptoms, later during the day he became restless, vomited a little, and complained of some abdominal pain. He died fifteen hours after the operation.

Remarks.—In this case there was much of interest: first, there was but little shock; second, the incision was above the umbilicus and bisected the track of the ball; third, there was extreme rigidity and retraction of the abdominal walls; fourth, resection of the gut was done; fifth, the intestines were with great difficulty returned to the abdominal cavity; sixth, the peritoneal toilette was imperfect; seventh, the incision was sutured with difficulty; eighth, there was violent delirium after being put to bed.

The absence of shock was prominent, and adds to the evidence that lack of this symptom should not have too much weight in estimating the injury done by a ball. The incision above the umbilicus, I believe, was unfortunate, for being near the muscular attachment the rigidity of the walls was great and the unyielding opening made it almost impossible to examine for or to repair the injuries. The incision had to be enlarged to 7 inches before the intestines could be returned, and even then they had to be punctured. Time could have been saved and manipulation lessened had the incision been, in the first place, below the umbilicus, and then, if necessary, extended up. Three of the perforations were so close that resection was deemed advisable; in a similar case I should suture the wounds, and if the calibre was too much diminished, should make an anastomosis above and below the constriction, using plates, as recommended by Dr. Senn.

The great difficulty experienced in keeping the intestines confined made it impossible to clean the peritoneal cavity. The delirium was due largely to whiskey; death to the extensive wounds, to the duration of the operation, and its necessary attendants, and probably occurred before there was septic peritonitis.

Case 3.—D. J., mulatto, æt. 29, was shot in the country on December 25th, at 10 o'clock in the morning. He was drunk at the time, and after receiving the wound walked several hundred yards. He came to Lexington in a wagon, and Dr. Willis was called to see him. I saw him at 2 P.M., and he was still quite drunk. There was no shock, and he complained little of pain. Two and a quarter inches to the left of, and a half-inch below the umbilicus was a bullet wound, and through it a probe passed into the abdominal cavity. An exploratory incision was decided upon, and everything gotten ready as quickly as possible. Assisted by Drs. Willis, Molloy, and Brock, I began to operate at 4 o'clock, six hours after he received the wound. Chloroform was administered, and an incision was made in the median line, between the umbilicus and pubis, about 4 inches long. A loop of the small intestines was brought into the opening, and starting from this point I traced the tube above to the duodenum and below to the cæcum, but found no injury. There being a little blood in the peritoneal cavity, it was sponged out and the incision sutured with silk. Boiled water filtered through flannel was the only kind used. The operation lasted about an hour, and the patient rallied promptly. Antiseptic dressings were applied and he was put to bed. During the night he became quite restless, vomited several times, and the temperature went up to 100. A $\frac{1}{2}$ grain of morphine was given by mouth, and he became quiet.

December 26th, 11 A.M.—Patient doing well; no pain; normal pulse and temperature. From this time everything was favorable; the stitches were removed on the ninth day; twenty days after the operation he returned to the country, against my advice, but when last heard from was well and doing hard work. After the first twenty-four hours small quantities of milk were given, and at the end of two days the food was gradually increased to its normal quantity. Castor oil was given on the fourth day and the bowels moved several times.

Remarks.—The location of the wound and the fact that the abdominal cavity had been entered, were my only reasons for opening the abdomen; then, an exploration, cleanly and carefully done, did not, in my opinion, add much gravity to the case. Senn's hydrogen-gas test for perforation might have been preferable to exploration, but I was not prepared to make it.

Case 4.—J. J., Negro, æt. 25, shot at 10 P.M. April 22; seen by me at 2 A.M. the 23d. Was

then resting quietly and with but little shock; no vomiting had occurred, and there was nothing to indicate serious injury. One and a half inches below the ensiform cartilage, and one and a half to the right of the median line, there was a bullet wound, which passed direct into the abdominal cavity. I left, with the instruction to have things ready for an operation at nine o'clock.

At 11 A.M., thirteen hours after the wound was received, I made an exploratory incision four inches long in the median line, from the ensiform cartilage down. On opening the cavity considerable blood and bile escaped; and introducing my finger I felt a wound in the liver. The ball had passed through the right lobe, a little to the right of the suspensatory ligament, and had cut one of the bile ducts; the gall-bladder was intact, but empty. Hæmorrhage continuing, I decided to plug the wound with bichloride gauze, but to do this I was forced to make a cross incision of two inches, which divided the right rectus muscle below the cartilage. I succeeded in stuffing gauze in the anterior part of the wound and in controlling the hæmorrhage; the end of the gauze was brought out at the upper part of the incision. The posterior part of the wound was hard to get at, and as but little blood came from it, I left it without interference.

The peritoneal cavity was irrigated with two gallons of warm water and sponged out fairly clean. The incision was closed with silk and a rubber drainage-tube put in; iodoform was sprinkled over the wound and bichloride dressings were applied. Chloroform was the anæsthetic; operation lasted one hour, and the patient rallied well. He did well for two days after the operation; jaundice was then marked, and he became restless and delirious. He continued in this condition until the 28th, nearly five days after the operation, when he died. Bowels were moved frequently with glycerine enemata; urine contained a great deal of bile.

Remarks.—Considering the quantity of bile in the peritoneal cavity, the shock was very slight. All agree that bile extravasation renders a case almost hopeless; several notable exceptions are, however, referred to in "Greig Smith's Abdominal Surgery." In one, forty-seven pints of what seemed to be bile were drawn from the peritoneal cavity by Thiersch. The hæmorrhage from the liver was successfully controlled by stuffing the wound with bichloride gauze. There was never the slightest abdominal tenderness or distension, and the temperature never exceeded 99. The patient suffered more with pain in the right shoulder than he did from the wound.

In my opinion this patient would have recovered had not the bile duct been cut, and I feel sure that his death was due to chokemia.

GENERAL REMARKS.

Dr. Coley, in the *Boston Medical and Surgical*

Journal, gives to Baudens, of France, the credit of having done the first laparotomy for penetrating shot wounds of the abdomen, in 1836. He says: "Baudens boldly opened the abdominal cavity, resected eight inches of the small intestines, and united the edges with the Lembert suture. Although the patient died on the third day, the autopsy revealed a wound of the cæcum which had not been discovered at the time of the operation, and fecal extravasation in the abdominal cavity. His second case proved to be a wound of the transverse colon. The abdominal wound was enlarged, intestine sutured, and the patient recovered."

Dr. Kinlock, of Charleston, S. C., did this operation in 1881; and Kocher, of Berne, Switzerland, had a successful case in 1883. In this country Dr. Bull, of New York, met with the first success in 1884. Since then many operators have entered the field, and in Dr. Coley's article he gives tables containing 74 cases, with 39.5 per cent. recoveries. Under the "let alone" management of such cases, the recoveries were less than 10 per cent. He also points out the importance of operating early; in those cases operated upon within twelve hours after the wound had been received, the per cent. of recoveries was much greater than in those operated upon later.

With such a difference in the mortality, there can no longer be doubt as to the propriety of opening the abdomen when penetration has occurred, and surgeons are almost unanimous in advising laparotomy when there is strong evidence of the viscera being wounded. I might go farther and say, the fact that a ball had penetrated the abdominal cavity in a location where visceral injury is probable, should justify the surgeon in making an exploratory incision, even when the symptoms indicate no serious damage. Dr. Jos. M. Fox reports a successful case where two perforations were found in the small and two in the large bowel, and the only indication for operation was "the fact that the ball was found to have entered the abdominal cavity."

There was but little shock in my second case when I was first called to him, and in the third none at all. In the second I found great traumatism; in the third, no injury had been done the viscera, but my exploration did no harm, and the patient made a rapid recovery. Others have opened the abdomen and have found no viscera wounded, but all of the cases, I believe, have recovered after the exploratory operation. In one case mentioned by Dr. Mears, in his article in the *Annual of the Universal Medical Sciences*, the counsel, to defend his client, plead on the ground that the attending physician had failed in his duty, by not opening the abdomen and repairing the wounded viscera.

We now have a reliable test for perforation of the alimentary canal by the use of hydrogen gas,

as recommended by Senn. Several cases have been reported where perforation has been demonstrated, and Dr. Senn reports a very interesting one in which, after closing eleven perforations, he was enabled to find the twelfth in the upper part of the rectum, by the gas continuing to escape when forced into the bowel. This patient recovered.

When first called to a case of gun-shot wound of the abdomen, the thing to ascertain is: whether the peritoneal cavity has been entered; and, to do this, it may be necessary to enlarge the bullet wound and follow it through the walls. I have met two cases recently, of abdominal wounds, where the cavity had not been entered, although the wound in each case was near the umbilicus, and in one there was considerable shock. In following the track of the bullet, important evidence may be gained by noting the direction taken, and this will aid us in estimating the damage done in the cavity if it has been entered. In doing laparotomy for penetrating wounds of the abdomen, we should be fully equipped, that every advantage for recovery may be given that the surgeon can possibly offer. Cleanliness here, as in all abdominal operations, is essential, and any neglect in cleansing ourselves, instruments or patients, is scarcely short of criminal.

Water, boiled and strained, will answer for the peritoneal cavity, and I prefer not to add an antiseptic; a 5 per cent. solution of carbolic acid is best to cleanse the hands and instruments. Operators are almost unanimous in advising the median incision in this operation, and there can be no doubt but in the large number of cases this incision will best serve the surgeon. Dr. McGraw, of Detroit, in an interesting article published in the *Medical Record*, on "Some Points on Laparotomy for Visceral Injuries," disapproves of the incision being so invariably made in the median line. He discusses this fully, and cites a case where the ascending colon was perforated, and he succeeded in easily suturing the perforation by enlarging the bullet wound over the colon; had he made the median incision this would have been impossible, without making the incision very long. Unless there is strong evidence, however that the ball has injured structures only far to one side, or that one of the immovable organs has been wounded in a part far from the median line, I should employ the short median incision; even a long median, if the viscera could be repaired through it, I should prefer to one considerably shorter to one side. An incision through muscles causes them to contract, the abdominal walls to become rigid, and manipulation difficult; and besides, through a small incision to one side it is almost impossible to make a clean peritoneal toilette.

In my second case the operation was prolonged and great difficulty encountered in returning the

intestines to the cavity, owing to the rigidity and retraction of the abdominal walls. I attribute this condition to having made the incision high up, consequently near the muscular attachments; and to the fact that the ball had plowed through the abdominal muscles to the right of the median line, and had caused them to contract tonically. If possible we should, as soon as the peritoneal cavity is entered, find the course taken by the ball, and by carefully examining the wound—I refer, of course, to those cases where there is but one—and noting it carefully, first at the point it enters the wall and then at the point it leaves it to enter the cavity, we will usually be enabled to form a good idea of the course that has been taken. Muscular contraction and change in the patient's position may cause a change in the relative position of the two openings; but frequently the information gained will be satisfactory. If the direction is ascertained, then only those viscera possible to be injured should be examined, and no others manipulated.

Should we be in doubt as to the course of the ball, it may be necessary to examine most of the viscera, and to do this a long incision will be necessary. To deliver the intestines, and keep them out any length of time, even when surrounded by warm towels, will cause marked shock, and if possible, only the loop being sutured should be out of the cavity, and it should be returned before another is delivered. Care in preventing intestinal exposure, and in manipulating but little, is very important. Dr. Senn observed that dogs would frequently die from shock after the intestines were exposed for a half hour, and I see no reason why it should be different with man. In most cases the jejunum and ilium must be examined, and it is best to catch up a presenting loop, and to trace the tube first in one direction and then in the other, using care to return the examined loop as the next is brought in view. An assistant can usually with sponges keep the opening closed and the intestines in the cavity, except the part being operated upon. In case of hæmorrhage the intestines must be delivered rapidly and the bleeding vessels controlled, as in my first case, and sometimes, owing to the rigidity of the walls, the intestines will be forced out of the cavity, as happened in my second case.

All other viscera in the bullet's course should next be examined, by sight if possible, if not by sight, by touch; and if injury be found, it may be necessary to enlarge the incision before suturing can be done. The Czerny-Lembert suture will close securely all perforations of the hollow viscera, and I prefer the continuous suture, as it can be applied more rapidly. Dr. Senn recommends that "omental flaps" be applied over the sutures after circular enterorrhaphy, among other reasons, it being an additional safeguard against extravasation. All wounds of the mesentery

should be carefully coapted and sutured. In those cases where the mesentery is extensively lacerated at its junction with the intestines, and the blood supply cut off, resection should be done. In resecting, we can use the Czerny-Lembert suture, or better than that, Jobert's invagination suture as modified by Dr. Senn. In wounds of the solid viscera, when the hæmorrhage can be stayed, the prognosis is more favorable. In liver wounds, uncomplicated by other visceral injuries, the majority of cases have recovered. To stop hæmorrhage, deep sutures should be used if possible; if this cannot be done, then the cautery should be applied or the perforation stuffed with iodoform gauze, as has been successfully done in a liver wound. If hæmorrhage continues from a wound of either the spleen or kidney, it may be necessary to remove the organ. Dr. Parkes lost a case from hæmorrhage from the kidney, his patient living twenty-four hours; and Dr. Keen removed a kidney successfully, his patient living fifteen days, death being then caused by gangrene of a contused wound of the mesentery setting up septic peritonitis. Should the gall-bladder be wounded and the bile extravasated, the prognosis is most grave, death being almost inevitable. Greig Smith, in his "Abdominal Surgery," mentions a case recorded by Paroisse, where a ball remained in the gall-bladder for two years before death. We may, in perforations of this viscus, either suture the perforation or do a cholecystectomy.

Wounds of the urinary bladder should be sutured, and if the peritoneal cavity is not infected by urine, the patient may recover.

Besides the cases above mentioned, I know of but one other laparotomy for gunshot wound of the abdomen in Kentucky, and that was a case reported by Dr. Isaac Warren, of Somerset. He operated twenty-four hours after the patient was shot. The small intestines were perforated five times; the patient died of peritonitis fourteen hours after the operation.

REPORTS FROM HOSPITALS.

SURGICAL CLINICS AT THE WESTERN PENNSYLVANIA HOSPITAL BEFORE THE STUDENTS OF THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

BY PROFESSOR J. B. MURDOCH,

SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL AND PROFESSOR OF CLINICAL SURGERY IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

[Reported by WILL. N. PRINGLE, M.D., a member of the Graduating Class.]

January 12, 1889.

AMPUTATION OF THE FORE-ARM.

We have a patient here this morning who has

had his hand traversed by a car-wheel. This happened about two hours ago, and illustrates, very forcibly, the condition in which you will find a limb after an accident of this kind. You will frequently hear people say when they see a contused limb that, "it was merely grazed by the flange." Now this is an impossibility. I think that all of you know that the flange of a wheel is on the inner surface of the wheel, and travels along the inner edge of the rail, so that in order to be "grazed by the flange" the limb must be traversed by the tread of the wheel, or his body must be entirely under the car. A limb may also be caught and pushed along in front of the wheel, for a short distance, and then thrown from the rail. This may cause a very extensive contusion, so that you may even be at a loss to know, whether, or not, the wheel passed over the limb. This you may always ascertain by examining the bone, which you will find crushed, and finally comminuted where traversed, by the wheel, but where the limb has been merely shoved in front of the wheel, and thrown from the rail, you may find the bone fractured, in several places perhaps, but you will not find it crushed into fine fragments.

Before the days of antiseptics, we used strips of adhesive plasters in dressing these wounds, we formed our flaps, placed a few sutures, then covered the stump with adhesive strips. We do not use the plasters now, but we sew up our wound a little more carefully. One reason why we no longer use plasters is because they make a filthy dressing, and another is, because of the septic material in the plaster. In those days we shaved the limb, carefully to facilitate the removal of the plasters, we still continue to shave the limb, not so carefully, however, and principally for the sake of cleanliness.

In amputations of the forearm, I prefer the modified flap operation. You grasp the limb between the thumb and forefinger, of your left hand, at the point where you intend to saw the bone off. You then make your flaps by making incisions between the points where your thumb and forefinger rest, on the limb. You then dissect up the skin, turning it up as you would the sleeve of your coat. I also like to include part of the muscle, because if you dissect the skin up by itself, you sever all of the little vessels that go to its nourishment. I prefer the modified circular operation, because you cut the arteries at a right angle, and you make a less wound in the skin. After you have turned the skin up sufficiently, you make a circular incision of the muscles, cutting everything down to the bone, then pass the knife between the bones, cutting the interosseous membrane. You then saw off the bones, and there is a right and a wrong way to do this. I begin by placing the heel of the saw on the radius, then draw it back, making a track for your saw.

After your saw is well started in the radius, depress the handle and make a start in the ulna, then return and sever the radius, and last of all the ulna. Do not saw rapidly as the ends of the bones may be burned by the friction of the saw. Bite off all sharp angles or points of bone, with the bone forceps. In controlling hæmorrhage, I twist large arteries, and for capillary oozing, hot water is generally sufficient. A drainage tube is then inserted, and the wound is closed. In wounds like this, I like the seamstress' stitch; do not make the mistake of using the glover's stitch, or the stitch used in sewing covers on balls, for seamstress' stitch; if you do, you will not bring your edges into close apposition. Do not sew up a wound too tightly. Always make allowance for more or less effusion and wound tension.

OPERATION FOR FISTULA IN ANO.

We have another case to show you, that of a man with a fistula in ano. These, as you know, are caused by traumatisms, foreign substances in the rectum, and various other ways. An abscess first forms in the vicinity of the anus, pus accumulates and travels in the direction of the least resistance, which is usually in the direction of the rectum, although they also frequently open externally. After they have once opened into the rectum, the irritation from fæces entering the canal, together with the movements of the bowel, and the contractions and relaxations of the sphincter ani, interfere continually with repair, and they do not heal until the sphincter ani is divided.

You notice about this anus a peculiar growth, resembling somewhat a rose in appearance, then a condylomata, or mass of syphylitic warts. These must be handled with great care, as they possess the power of inoculating syphilis through a wound in the skin, or through an abrasion on the hands of the operator. You also see an opening in the skin on the left of the median line, and two inches from the anus. This is the external opening of the fistula, a grooved director passes in at this opening, and readily passes through and out at the anus. The director now lies in the track of the fistula, and with a scalpel I will incise all of the tissue that is lying over the director. This constitutes the operation for fistula in ano.

I find another small opening in the skin, on the right hand side of the median line, and about two inches from the anus. In this case I am unable to find an internal opening, but as the part is all undermined here with pus, I will make an internal opening, by forcing the director through into the rectum. This side will be incised as was the other. The after-treatment of these wounds, will be of more importance, than the operation. They must be kept thoroughly cleansed by frequent washings with antiseptic fluids, and they must be kept packed with iodoform gauze,

in order that repair may take place from the bottom. These condylomata will be removed by the scissors, and their seat cauterized, and when they begin to granulate they will be occasionally touched with nitric acid, nitrate of silver, or other caustics. This man will be put upon proto-iodide of mercury, which will be pushed until his gums are slightly touched, and if he does not improve on this he will be given mixed treatment. A favorite plan of mine is to take a piece of blue ointment the size of a chestnut, and rub it into his back, and repeat this each evening. This, together with the exhibition of iodide of potassium internally, I consider an excellent mode of treatment.

January 19, 1889.

OPERATION FOR HARELIP.

I have to-day a case of harelip to show you. The patient is a boy about 6 years old, and is brought here for operation by his father. Besides the harelip, he has a cleft of the palate. Instead of the double fissure in the lip as is often the case, he has but a single fissure, and where this is the case, it is almost always on the left side. You have seen Professor King operate on several cases of harelip during this term, but my manner of operating is somewhat different from that of Professor King. As a preliminary step I pass a loop of string, or ligature, through the lower angles of the lip, on either side of the cleft, not for any part it takes in the operation, but for the purpose of holding the parts out of the way. This is better accomplished in this way, than it could possibly be by the aid of forceps. I then dissect the lip loose from the superior maxillary bone, on either side of the fissure, so that they may be drawn together with greater facility, in closing the fissure. The next step in the operation, is to pare or denude the edges, that are to be brought into apposition. This is done by transfixing the lip just at its vermilion border, or just where the skin and mucous membrane meet. This should be done with a narrow, straight bistoury. The incision should then be carried well up to the nostril or to the extreme limit of the fissure, then cut off. The other side of the fissure, is then to be treated in like manner, and the two thin strips that have been pared off brought down so that they hang in front of the mouth. This constitutes the third step in the operation, and the loops through the angles of the lip, having subserved their purpose, are now removed. The lips having been previously dissected loose from the superior maxillary bone, are readily brought together, closing the wound. Here also surgeons differ, in the manner of retaining the parts, some prefer the wire suture, passed through the lips, while others prefer the silk or horse-hair ligature. For my part I prefer the harelip pins and a cotton cord ligature. I

prefer the cotton ligature, because it is a little more elastic, and a little softer, and not so likely to cut into the tissues. The first pin is passed just at the vermillion border of the lip, it should go deeply into the tissues of the lip, but should not include the mucous membrane of the mouth. It should pass across the wound, and emerge from the skin, at a point corresponding exactly with the point of entrance on the opposite side. The other pin is passed in like manner, near the upper border of the wound. It is not necessary to wait, for the hæmorrhage to cease entirely. Bringing the parts together with the pins, is usually sufficient to stop the hæmorrhage, if any remain.

You now notice a projection downward in the line of the wound. This is caused by union of the two strips pared from the sides of the fissure, and they will be made to fulfil a good purpose here, because in a great many of these operations a notch is left after the wound heals. In this case, part of this projection will be left here, so that after repair has taken place, enough of it will remain, to prevent a notch being formed. Now in addition to the two pins, I will put a wire suture through the wound, for additional support, and two or three sutures of fine silk, through the mucous membrane of the projecting part, to hold it in apposition. The pins should not be allowed to remain too long, or they will leave marks, after the wound has healed; on the other hand, if they are removed too soon the wound may come apart, so it is a very nice point to know just when to remove them. Mr. Holmes asserts that he removes the pins in twenty-four hours, while others allow them to remain for several days. There is no rule in regard to this, but they should be removed as soon as they can be dispensed with. I cut off the heads, and points, of the pins, and to prevent the projecting parts from sinking into the skin, I put small bits of plaster under them. For additional support, I draw narrow strips of adhesive plaster over the wound, from side to side.

THE OPERATION OF CIRCUMCISION.

I have another case to show you to-day, that of circumcision. It is said that this operation was first done by Moses, but I believe that it was done in Arabia, long before the time of Moses. At all events you know that there are fashions in surgical operations, as well as in the cut of your wearing apparel. This operation seems to have again come in fashion, within late years. A long prepuce of course is an annoyance, to a man all through life. Besides that from phimosis, and paraphimosis, it is exceedingly filthy, and frequently leads to disease. There is, however, some points in favor of the long prepuce. It was put there for some good. Without it the meatus may become contracted from friction with the

clothing. In covering the glans it serves to keep that part more tender, and sensitive, thus rendering copulation more desirable, and conception more certain. Therefore I think that the operation should not be advised unless there be some good reason for it, other than that of being in the fashion.

This boy, about 15 years old, has been in the medical side of the hospital for some time. A few weeks ago, it was noticed that he became nervous, restless and sleepless. Later he became delirious, which continued until he had to be confined to the cell. An examination showed that he had a very long prepuce, and phimosis. I do not know that this is the cause of his nervous trouble, but our reason for doing the operation is based on sufficient absolute authority, to justify us in doing it. Do not think, however, that every boy with a long prepuce has phimosis, or even an abnormality. This is the normal condition in young boys. In doing this operation, it is well to make a mark with ink at the point where you intend to divide the foreskin. The part is then placed between the blades of Ricord's forceps, and all in front of the forceps is cut off. The skin is then reflected behind the glands, but the mucous membrane will remain. This is then cut or torn, and reflected back with the skin. The skin and mucous membrane is then sutured together, and this is usually done with the horse-hair suture. In the Jewish rite, the Rabbi does not sew the skin and mucous membrane together, and I would not advise you to do it, in very young children. This constitutes the operation. This boy will be given medical treatment, and it remains to be seen what effect it will have on his reason which, as I told you, is entirely lost.

MEDICAL PROGRESS.

ON THE PROGNOSIS OF HEART DISEASE.—LEYDEN reverts once more to the question how long the period of complete compensation of a cardiac lesion can last. Supposing, for instance, that in a patient with cardiac lesion the compensation is altered. This alteration admits of three phases:

1. It is slight and manifests itself only by inability to work.
2. The trouble of compensation is complicated by dropsy.
3. Dropsy is accompanied by visceral congestions, asystole, etc.

This latter phase is beyond the physician's skill; only the first and second are susceptible to therapeutic measures.

The first question to be asked is regarding the cause of the break in the compensation; whether it is the result of a progress of the cardiac lesion

or of an accidental cause: fatigue, excess, over-feeding, additional disease, gravidity, etc. A conclusion of the utmost importance for prognosis may be drawn from the effect of the cardiac medicines, from which we may easily judge of the condition of the cardiac muscle. Oertel notes in his cardiac patients the daily quantity of liquids introduced and excreted, as in these cases the prognosis depends largely upon the difference between the introduction and excretion of liquids; the greater this difference the less favorable is the prognosis. The same inference may be drawn from the action of digitalis: the prognosis varies according to whether this substance acts rapidly or slowly, or not at all.

As regards physical symptoms of heart disease I have already stated that changes in the volume of the heart must especially be noted. While the heart tones have no especial prognostic value it may be said, in a general way, that the systolic murmur is less grave than the diastolic. It is certain that in many cases systolic murmurs may exist without a trace of cardiac lesion. To be sure, it is necessary to distinguish here between the systolic murmurs of the orifice of the aorta and those of the apex of the heart, as in individuals of a certain age the systolic murmurs of the aorta lead always to a suspicion of an alteration of the aorta. The prognosis of the systolic murmurs of the apex is, therefore, better. On the other hand, the diastolic murmurs indicate, except in very rare cases, the existence of an organic lesion. To be sure, there are accidental diastolic murmurs, but they are so rare as to be safely ignored for our present purpose.

Let us examine now the anomalies in the rhythm of the heart without organic lesion. The intermittence of the pulse with increase in strength at the moment of resumption induces individuals thus affected to believe that they have heart disease. I do not attribute the least significance to this symptom, which is due, I believe, to a psychical cause or to reflexes originating with the organs of the abdomen. Equally frequent is the arrhythmic pulse. There are persons who have had an arrhythmic pulse all their lives without being troubled thereby in the least (provided there is no manifest organic lesion of the heart). I consider the prognosis in such a case favorable, but the complete disappearance of this arrhythmia is very rare.

Delirium of the heart (or, as ancient authors call it, *tremor cordis*, because the rhythm could not be perceived), is a more serious affection. It cannot last very long without affecting the heart seriously.

Tachycardia, that is, a perceptible increase in the frequency of the pulse, depends physiologically upon a paresis or a paralysis of the vagus nerve. It is admitted that prolonged increase above 120 pulsations is dangerous, but 130 to 140

pulsations have been observed without death following. I observed once a pulse of 140 for four weeks, at the end of which period the patient died. In individuals affected with Basedow's disease the frequency of the pulse is always very great; above 160 it becomes dangerous to life. Once I saw a pulse of 200 in a patient affected with Basedow's disease, who died a few days afterward. In tachycardia febrilis the prognosis becomes serious as soon as there are more than 120 pulsations a minute. This kind of tachycardia may vary a great deal with different individuals and according to the disease. It is hardly necessary to mention the great frequency of pulse during the first period of acute exanthemata without the prognosis being unfavorable on account of it. There exists also a paroxysmal tachycardia in this sense, that the rapid pulse appears only at intervals; it is frequent in neuroses of the heart, and not dangerous because transitory. Tachycardia in convalescents appears in consequence of the slightest psychical or physical effort.

Bradycardia is seen in patients with icterus, and is generally rather a serious symptom. The bradycardia following the administering of digitalis, as also that which complicates angina pectoris, are well known. Physiologically, I mention here that ligature of the coronal arteries produces likewise a bradycardia. When patients are required to take digitalis for a long time the frequency of the pulse diminishes. Permanent bradycardia: that is, the rapid slackening of the pulse which falls to 30 or even 20 pulsations, was first described by Stokes; it is complicated with syncope, convulsions which seem to result from anæmia of the brain.—*La Semaine Médicale*, May 15, 1889.

L'HYDROXYLAMIN IN DERMATOLOGY.—P. J. EICHHOFF, in *Les Nouveaux Remèdes*, recommends this substance for the treatment of skin diseases. It appears in the form of colorless hygroscopic crystals, easily soluble in water, alcohol and glycerine. It is an active reducing agent, forming in the blood methæmoglobin. It produces hæmaturia by destroying the blood corpuscles when introduced into the blood in doses exceeding 1 centig. for each kilogr. of animal. Besides it acts as a narcotic on the nerve centres. Because of its pronounced reducing qualities this substance recommends itself as an excellent topical application in parasitical skin diseases. Eichhoff especially likes the chlorhydrate in the following formula:

Chlorhydrate of hydroxylamin . . . 0.1 gr.
Alcohol or glycerine 50.0 gr.

For external use.

After washing the affected portions of the skin with soap they are painted from three to five times daily with the alcoholic solution of hydroxylamin. This alcoholic solution being very irritating and poisonous, at the beginning no

stronger solution than 1:1,000 should be used, and not until later, when no harmful secondary symptoms have developed, may a stronger solution be resorted to. Eichhoff treated in this way five cases of lupus vulgare, five cases of herpes tonsurans, and one case of parasitical sycosis of the face. The results were especially encouraging in lupus; even after eight days of treatment a reduction of the hypertrophied portions was noticed, and a cure with smooth scar was effected inside of four weeks. In herpes tonsurans the hydroxylamin at first greatly irritates the skin, but the final result is none the less satisfactory. The author intends to use the substance also in other diseases, such as psoriasis.—*Journal de Médecine de Paris*, May 12, 1889.

PUERPERAL FEVER.—DR. A. HACHSTEIN, in *American Lanct*, says: The whole substance of the prevention of puerperal septicæmia is: Do not allow any poison to be near a puerpera, or if there is any do not permit it to enter her genital tract. But if regardless of all our precautions the poison has entered the genital tract, destroy it before it gets into the system.

This latter is the whole essence of therapy in this disease. Thus the most efficacious treatment will be a local one. Disinfecting vaginal injections will remove the poison from the wounded structures in the genital canal, and at the same time ward off the immigration of new poisonous matter. If pieces of membrane or of the placenta are left in the uterine cavity to decay, intra-uterine irrigation used two or three times will do the best service; if not sufficient, curetting should be resorted to. If the poison has entered the system, and we have to deal with general peritonitis, laparotomy should be taken into consideration.

In general treatment we all have been accustomed to rely greatly on opium. As for my part, if I had to treat a case of puerperal septicæmia now, I would not seal up the primæ viæ and so allow the ptomaines to remain in the system, by giving the opiates; but I use the salines from the beginning.—*Archives of Gynecology*, May, 1889.

THE DISAPPEARANCE OF CARDIAC MURMURS.—DR. M. A. BOYD, of Dublin, at a recent meeting of the Royal Academy of Medicine in Ireland, read a paper on the disappearance of cardiac murmurs which have existed sufficiently long and have led to such changes in the cardiac walls as to be considered organic in character. Such disappearing murmurs are generally consecutive to acute rheumatic endocarditis; cases also occur of chronic endocardial changes which ultimately leave the heart free from all traces of disease. Dr. Boyd gave three instances of cases under his own observation—one of the murmur of mitral regurgitation, with consecutive changes in the

left ventricle and auricle, which existed for two years, and ultimately disappeared, as did the hypertrophy associated with it; and two others of aortic regurgitation existing for a considerable period, which finally got quite well also. In both these latter cases the existence of hypertrophy and dilatation of the ventricle might be taken as sufficient evidence that they were of a permanent nature, as also the length of time they continued after the primary endocarditis. A well-established constrictive murmur, in his opinion, never gets well: it may disappear or cease to be heard, owing to failure or weakness of the cardiac walls, or to excessive dilatation either of these or the aorta, but the symptoms associated with it remain, and *post-mortem* evidence shows no cure. Plastic material deposited on or in valves may ultimately get absorbed when it only interferes with their adaptation, but when deposited around the margin of an orifice it must ultimately, by its contraction, cause obstruction. Such absorption is most likely to take place in young subjects, owing to the rapid metabolic changes which occur in their tissues and to compensation being more easily established; and is more frequent where the valvulitis is rheumatic than where it is the result of alcoholism, gout, or contracted kidney.—*The Medical Press*, March 13, 1889.

PRECOCIOUS MENSTRUATION: AMENORRHEA WITH CONVULSIONS.—A case of remarkable precocious menstruation is reported by DR. DIAMANT, of Vienna. When a 12-month old, the child had cut all her milk teeth. When barely 2 years of age, the first period was observed. It lasted four days, and recurred with regularity till the child was 6 years old. At that age her breasts, loins, and pelvis were of the adult type; the axillæ and pubes were thickly covered with hair. Suddenly the period ceased, and for six months after the child had completed her sixth year epileptiform convulsions came on during sleep, at every date when the catamenia should have appeared. The fits some times lasted three-quarters of an hour, and increased in number every month. They were continuing when the case was reported, the child being then 6½ years old.—*British Medical Journal*, May 4, 1889.

PHENACETIN IN LOCOMOTOR ATAXIA.—HOTTENSTEIN, records the case of a man, æt. 64, who had a syphilitic history with typical progressive locomotor ataxia, accompanied by exceedingly severe lancinating pains in the legs, arms, and face, as well as the abdomen. In some attacks the bladder and genito-urinary tract were especially involved in the nerve-storm, and violent tenesmus was often present. Phenacetin, in the dose of 28 to 32 grains at the beginning of an attack, always brought relief in less than one hour.—*University Medical Magazine*, Jan., 1889.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, JUNE 15, 1889.

RAILROAD RATES.

We regret to say that the Committee of Arrangements has been unable to secure special rates for those who wish to attend the meeting at Newport. Every reasonable effort has been made to secure reduced rates, and we feel confident that the action of the railroads has not been in accord with their own financial interests. On all these roads excursion rates are given, and doubtless in many cases these may be made available.

MASSAGE IN GYNECOLOGICAL PRACTICE.

A great deal of interest is being manifested of late in the treatment of uterine displacements and inflammatory exudates surrounding the female pelvic organs, by means of what may be called (for want of a better term) pelvic massage.

The principles involved in this method of treatment and their actual application in gynecological practice, while scarcely to be regarded as new have nevertheless only just begun to attract anything like general interest on the part of the profession. For some years past articles descriptive of the application of the methods, with accounts more or less credible of the cures achieved, have appeared in the literature of gynecology and in the near future the subject will doubtless have a literature of its own.

One of the earlier papers on this subject and one that has attracted considerable attention both at home and abroad, is that by Prof. A. Reeves

Jackson, of Chicago, entitled "Uterine Massage as a Means of Treating certain Forms of Enlargement of the Womb." This paper was read before the American Gynecological Society, in 1881. Very recently Prof. Jackson has expressed himself as thoroughly convinced of the efficacy of the method when properly employed. He believes, however, that it requires the manipulations of the skillful gynecologist himself, to secure anything like satisfactory results and that it is quite useless to relegate the patient to the hands of even the most skillful and painstaking nurse.

At a recent meeting of the Chicago Gynecological Society, Prof. F. H. Martin spoke of the method in warm terms of praise.

At the meeting of the Royal Academy of Medicine in Ireland, April 12, 1889, Dr. Alfred Smith reported the results attained by massage and pelvic gymnastics in six cases of prolapsus uteri. Although his results were not positively brilliant they were, notwithstanding, sufficiently satisfactory to encourage the reporter in the belief that the procedures in question possess a very high degree of efficiency. In the ensuing discussion all who participated, among them Dr. Atthill, expressed themselves as satisfied of the potentialities for good of these plans of treatment, which they welcome as important additions to the therapeutics of conservative gynecology.

In a recent discussion at a Congress of Russian physicians, a large number of cases of prolapse and displacements of the uterus treated in this manner were reported and much enthusiasm was manifested with regard to the results attained.

But it is not necessary to multiply reports of this character. Enough has already been said to indicate the widespread interest manifested. The universal expression of opinion is one indicative of great satisfaction that such a powerful adjuvant to the more familiar practices of conservative gynecology has been discovered.

But singularly enough, and little to the credit of professional gynecologists, this wave of enthusiasm was started by an outsider, so to say, for all unite in yielding the palm to Thure Brandt, of the "Central Institut" for gymnastics in Stockholm, who is not a physician at all, much less a gynecologist!

A very complete and extremely interesting description of Brandt's "hygienic-gymnastic treatment," as it is termed by the Germans, is con-

tained in a very recent publication by Dr. L. Fellner, of Vienna, in the *Klinische Zeit- und Streitfragen*. Dr. F., after having been for two months under the instruction of Brandt, returned to his home full of that kind of enthusiasm which is always infectious, though often somewhat disappointing in the end.

Brandt himself, it seems, had been actively engaged in massage from the year 1844, when in 1847 he was fortunate enough to cure a case of prolapse of the rectum. Later on, in 1861, he made a remarkable cure of a case of prolapsus uteri of twenty-seven years' standing, after a two weeks' course of treatment. This woman, he says, remained free from prolapse until her death which occurred twenty-three years later. Since then his experience with the various forms of uterine displacement and exudates, has been very extensive although for many years his results attracted comparatively little attention from medical men.

However, in 1887, his work having come to the notice of several physicians of eminence, he was introduced through the instrumentality of Profanter, to Prof. Schultze, of Jena, at whose clinic he was accorded full opportunity to display his remarkable abilities both in the direction of gynecological diagnosis and mechanical treatment. This he did to the complete satisfaction of Prof. Schultze and a number of other gynecologists who witnessed his manipulations and have since borne witness to their surprise and gratification in most cordial and unmistakable terms of praise. The reports of the cases treated by him at Schultze's clinic, were published in detail by Profanter together with an introduction by Schultze himself, under the title of "*Die Massage in der Gynäkologie von Dr. Paul Profanter*" (W. Brannmüller, 1887).

This was the real beginning of Brandt's fame; for following Profanter's publication, gynecologists began to crowd in on him to learn his methods and from them, and in turn their pupils, emanate the glowing reports which are becoming so frequent in current literature.

Brandt's treatment includes the following procedures:

1. Various active and passive movements pertaining to the so-called Swedish Movement Cure. These are generally entrusted by him to a female assistant, who applies them according to instruc-

tions which are varied to meet the exigencies of each individual case. These do not (so his pupils say) constitute essential features of a rational treatment and may be supplanted by the various hydropathic drink and bath cures dear to the heart of the true German physician!

2. Massage.

3. Stretching.

4. Replacement of the uterus (Redression).

5. Elevation of the uterus (Uterushebung).

6. Pressure upon the pelvic nerves.

7. Abduction and adduction (against resistance) of the knees.

8. Slapping of the back and tapping of the loins and sacral region (tapotement).

Massage finds its application in cases of swelling and thickening of the organs and tissues occurring as a sequence to stasis, chronic inflammations and extravasations, as well as in subacute and acute inflammation.

Stretching is never employed in cases of acute and subacute inflammation, nor in cases of exudation. It is only indicated in cases where the ligaments are relaxed and lengthened, or shortened and contracted.

The recognized indications for massage are: metritis and endometritis chronica, subinvolution of the uterus, hypertrophy and atrophy of the uterus, parametritis, perimetritis, perioöphoritis, salpingitis, pelvic cellulitis, hæmatocele and uterine displacements, in all of which it may be employed as an auxiliary mode of treatment.

The object of stretching is to lengthen the shortened ligaments and to restore tonicity to those that have become relaxed. This procedure is never undertaken during the progress of inflammation, or in the presence of exudates. The principle involved in stretching is that a muscular irritation of short duration excites contraction, while an irritation of continued action induces elongation.

Replacement of the uterus. This is accomplished by various methods and with the patient in one of several positions—standing, knee-elbow, or lithotomy. The recto-vaginal method of replacement is employed in cases where the uterus is enlarged and retro-flexed. The operation is performed with the patient in the knee-elbow position. The operator's finger is introduced into the rectum and the thumb into the vagina, whereupon the fundus is pressed forward and downward

while the cervix is pushed backward and upward.

Ventro-vaginal replacement is practiced in the lithotomy position and is accomplished by the methods of tilting, invagination of the abdominal walls, hooking in of the finger behind the fundus and by the so-called replacement pressure. Tilting is used when the uterine walls are so rigid that pressure on the anterior surface of the cervix suffices to raise the fundus until it can be grasped by the other hand through the abdominal walls. The invagination process is resorted to when the uterus cannot be tilted forward. The fingers of the external hand are made to push back, "invaginate," the walls of the abdomen until the fundus is brought within reach, while the finger of the other hand introduced into the vagina presses the portio vaginalis backward and upward. In this manner the uterus is brought into a position of anteversion.

The "hooking" process referred to, is that which is employed when the uterus is so flexible that pressure on the vaginal portion increases the angle of flexion. The finger is introduced behind the fundus which is pressed towards the abdominal walls until the external hand is able to obtain hold of it.

The "replacement pressure" is exercised when the portio vaginalis is firmly fixed anteriorly. The internal finger presses up on the fundus and holds it in position, while the fingers of the external hand press down over the symphysis upon the isthmus uteri forcing it backward. Thereupon the internal finger of the operator is changed to the anterior surface of the cervix, close under the fingers of the external hand, and for several seconds pressure is made by both hands in a backward direction. Then while the internal finger still continues its pressure, the external hand is made to glide over the anterior surface of the uterus until it reaches the superior margin of the body, when it is turned until the finger-tips are directed forward, when they are made to sink behind the fundus which is then brought into anteversion.

Ventro-vaginal-rectal replacement. This method is adopted when the fundus is so high up that it cannot be reached by the internal finger, in which case it becomes necessary to make it more accessible by downward pressure exercised by the disengaged hand. The patient is placed in the lithotomy position. The left index finger is next

introduced as high as possible into the rectum. The fingers of the disengaged hand are then laid upon the abdomen in the vicinity of the fundus and made to execute, under moderate pressure, a circulatory rubbing motion in the direction of least resistance while the effort is made to bring the fundus gradually downward and forward. If it is not possible in this way to reach the posterior surface of the uterus, the effort is aided by the introduction of the left thumb into the vagina the index finger meanwhile remaining *in situ*. The thumb is then employed to press the cervix backward, while the index finger raises the fundus until it can be grasped by the fingers of the unemployed hand when it is in this manner brought into place.

Our limits do not permit the completion of the discussion of this subject in the present issue of THE JOURNAL. In the next number we propose to discuss the method ascribed to Brand, and which no doubt originated with him. The importance of the subject is such that it merits the careful consideration of the profession.

SECONDARY STREPTOCOCCUS PNEUMONIA.

In continuation of his study of diphtheria, PRUDDEN publishes his promised researches on the etiology of pneumonia.¹ He finds uniformly in the fresh exudate in the air-vesicles of the lungs of children dead of diphtheria the same streptococcus which was always present in the pseudomembrane in the throat. As control experiments, the exudates from cases of pneumonia in children, not secondary to diphtheria, were similarly examined, and in only one case was a streptococcus found, and then in a case complicating erysipelas. The presence of the streptococcus in these pneumonias is adequately demonstrated, and there can be no doubt that it is the prime and essential etiological factor of the local disease. The relation of the streptococcus to diphtheria, however, is probably secondary and non-essential.

These researches on the etiology of secondary pneumonia in diphtheria are in perfect accord with the investigations of the bacterial condition of pneumonias secondary to other infectious diseases. We may refer to Newmann (1886), Manfredi, Tobeitz and A. Fränkel (1887), Guarnieri (1888),

¹ T. Mitchel Prudden and William P. Northrup: Studies on the Etiology of Pneumonia Complicating Diphtheria.—"The American Journal of the Medical Sciences," June, 1889.

and Babes and Raskin (1889). Each of these authors reports pneumonias, secondary to the various acute infectious diseases, the prime etiological element of which was a streptococcus. Fränkel very properly pointed out that the microbe gains access to the body through the atrium furnished by the local lesion of the primary disease.

Babes and Raskin have shown conclusively that the nephritis and synovitis, as well as the pneumonitis which follow the acute infectious diseases of children, are due, in the great majority of cases, to a secondary infection, with the *streptococcus pyogenes*.

While it is greatly to be deplored that any single institution can furnish the material for such extended researches as these of Prudden and Northup, we may take a measure of consolation from the fact that the enthusiasm and scientific courage have of the pathologists have wrung out of wholesale disaster such an important lesson. Let the medical profession recognize in the complications of the acute infectious diseases, a septic process as independent and foreign to the primary disease as suppuration and erysipelas are to the reparative process in wounds, and we shall not wait long for a method of treatment which will banish them to the seclusion which has been sought by the wound diseases and puerperal fever.

THE OPHTHALMOSCOPE.

The ophthalmoscope, at one time considered as nothing but an interesting scientific toy, has become an indispensable instrument in physical diagnosis. Its history is a succession of triumphs. The wonderful progress made within the last thirty years in ophthalmology is altogether due to this instrument. By its means the neurologist has been able to penetrate the mystery which enshrouded many cases of brain and spinal disease, and our knowledge of kidney diseases, secured from the ophthalmoscope a valuable contribution when it revealed the existence and nature of the various forms of ocular disturbances concomitant with and due to nephritic disorders. In view of these facts should not the use of so important an instrument be thoroughly taught in our medical colleges? Should not every physician be equipped not with the instrument alone, but with the knowl-

edge and experience necessary for its practical use. Yet how far we are from this state of things. How few of our graduates know how to "throw light into the eye," and of these how small the number who know what they see in the field thus illuminated. If these men only knew enough to know what they don't know, the case would not be so bad, but ignorance is proverbially arrogant, and hence the mistakes of the ignorant are prone to escape correction. It is really humiliating to witness a graduated physician attempting to examine an eye while the light reflected from the mirror is seen illuminating the wall beyond the patient's head, and how often serious blunders in diagnosis occur is best known to those who have had an opportunity to watch graduates at work with this instrument.

A more thorough instruction in the use of the ophthalmoscope is imperative, and our medical colleges should see to it that the student be thoroughly trained in its use. Of course it cannot be expected that the general practitioner shall be an expert, that should be left to the oculist, but every medical man should at least be able to recognize the difference between a transparent and an opaque lens, a normal papilla and a choked disc, and a healthy retina and one affected with retinitis. Then will men be able to recognize also their limitations, and serious blunders will not be so common. Until this condition of things is brought about we cannot lay claim to that high standard of medical education which should characterize the curriculum of the American medical colleges.

THE DISASTER.

The sympathies of the Nation for the past week have been centered upon the sufferers of the Conemaugh Valley. Ten days have now elapsed since the occurrence of that fearful calamity. The actual condition, sad as it is, is less appalling than at first reported. A conservative estimate reduces the number of dead to about five thousand. From the bulletin issued by the State Board of Health, on June 9th, we learn that the general health in the region of the disaster is excellent; that there is no evidence of epidemic disease; that the whole country has been districted and each section placed under control of a competent sanitarian—and it is confidently believed that the work of reclamation will be carried on so rapidly

and so well that the general health in the locality will be maintained. This is well, and we heartily commend the State Board of Health for this efficient action.

But the question which we wish to emphasize is this: Who is responsible for this wholesale destruction of human life? Had the Valley been devastated by a volcanic upheaval or had a cyclone swept it to destruction, human agency would not be responsible for that which it could not control. But here it is not so. The primal cause of this calamity was the work of human hands. It was legitimately under the surveillance of sanitary inspection. It could have been averted by legitimate authority and somebody is responsible for the loss of these five thousand lives.

EDITORIAL NOTES.

UNIVERSITY OF PENNSYLVANIA.—We learn from a contemporary that the Associate Professorship of Obstetrics in the Medical Department of this University, recently vacated by Dr. Howard A. Kelly who has accepted the appointment as Gynecologist to the Johns Hopkins Hospital, is not likely to be filled. It is understood that Dr. Barton C. Hirst, the present Associate Professor of Obstetrics, will also undertake the duties of Gynecologist.

A TESTIMONIAL FREE BED.—The friends of Dr. R. J. Levis, of Philadelphia, the well-known surgeon to the leading hospitals of that city, are desirous of recognizing his distinguished public services by perpetually endowing a testimonial free bed in the Polyclinic Hospital. A committee, during his absence in Europe, are endeavoring to raise \$5,000 for this purpose, and think it is eminently appropriate that the testimonial should be donated to the Philadelphia Polyclinic since he was one of its founders, its first professor of clinical and operative surgery, and from its organization has been president of the board of trustees.

The Committee having charge of raising the desired amount request that subscriptions be sent to Dr. H. Augustus Wilson, Treasurer, 1611 Spruce St., Philadelphia.

THE PHYSICIANS OF CINCINNATI and of that vicinity are making up a special train of palace cars, for the purpose of attending the meeting of the American Medical Association at Newport.

The President of the Association, Dr. W. W. Dawson, will be a member of the party, and the coach assigned to him is designated—*the President's car*.

MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.—The following changes have been made in the Faculty: Frank Woodbury, A.M., M.D., Honorary Professor of Clinical Medicine. William B. Atkinson, A.M., M.D., Honorary Professor of Sanitary Science and Pædiatrics. John V. Shoemaker, A.M., M.D., Professor of Materia Medica, Pharmacology, Therapeutics and Clinical Medicine. James M. Anders, Ph.D., M.D., Professor of Hygiene and Clinical Diseases of Children.

MEDICO-LEGAL SOCIETY OF CHICAGO.—The annual meeting of this Society, was held on the 1st inst., when the following officers were elected for the ensuing year: President, Dr. E. J. Doering; Vice-Presidents, Dr. Boerne Bettman and Mr. Eric Winters; Treasurer, Dr. L. L. McArthur; Secretary, Dr. Edward B. Weston. Surgeon-General John B. Hamilton, of Washington, was elected an honorary member, and Drs. J. C. Hoag and H. J. Tillotson active members.

TENTH INTERNATIONAL MEDICAL CONGRESS. We are reliably informed that the Tenth International Medical Congress, to be held in Berlin, will commence on the 7th of August, 1889. The preliminary arrangements are in active progress.

We are advised that Sir James Grant and several other distinguished Canadians, have accepted the invitation to be present at the meeting at Newport.

AMERICAN LARYNGOLOGICAL ASSOCIATION.—At the Eleventh Annual Congress of this Association, held in Washington from May 30 to June 1, the following were elected officers for the ensuing year: President—Dr. J. N. Mackenzie, Baltimore. First Vice-President—Dr. Edgar Holden, Newark. Second Vice-President—Dr. C. E. Bean, St. Paul. Secretary and Treasurer—Dr. C. H. Knight, New York. Librarian—Dr. T. R. French, Brooklyn. Council—Dr. Franklin H. Hooper, Boston; Dr. George M. Lefferts, New York; Dr. Frederick I. Knight, Boston; Dr. D. Bryson Delavan, New York. Representative on the Committee of the Congress of American Physicians and Surgeons—Dr. Harrison Allen, of Philadel-

phia. Dr. Wm. C. Casselberry, of Chicago, and Dr. H. L. Swain, of New Haven, Conn., were elected to membership.

ASSOCIATION NEWS.

American Medical Association. Fortieth Annual Meeting.

The following additional titles of papers to be read at the approaching meeting have been received since the Programme was published in THE JOURNAL of June 1:

Section on Dermatology and Syphilography.

"Clinical Notes on Alopecia Areata," by Lewis Wickham, of the Hôpital St. Louis, Paris, France.

"General Points on the Treatment of Inflammatory Diseases of the Skin," by Oscar Lassar, Berlin, Prussia.

Exhibition of Specimens illustrating Change of Color in the Hair from the Internal Use of Pilocarpine, by D. W. Prentiss, Washington, D. C.

"Two Years' Experience with the Hypodermatic Injection of Insoluble Mercurial Salts in Syphilis," by J. N. Bloom, Louisville, Ky.

"Treatment of Syphilitic Glands by Injection of Iodine," by Fayette Dunlap, Danville, Ky.

"Eruption produced by the Internal Use of Rhubarb," by H. Goldenberg, New York.

"The Influence of Clothing on the Skin," by J. Leslie Foley, Boston.

Section on Surgery and Anatomy.

"What Dressing shall lie Next to the Womb?" by R. T. Morris, New York.

"Cranial Surgery," by H. O. Walker, Detroit.

"Unique Case of Fractured Exostosis of Pubis," by Thos. H. Manley, New York.

"Improved Surgical Pump," by Elmer Lee, St. Louis.

"The Surgery of the Spine," by Wm. White, Philadelphia.

"Incomplete Inward Dislocation of the Radius and Ulna at the Elbow," by Albert F. Stifel, Wheeling.

Section on Ophthalmology.

"Insufficiency of the Recti Muscles, with Report of Cases," by J. E. Colburn, Chicago.

In the published programme for this Section the title of Dr. P. D. Keyser's paper appears "Glaucoma Fulminans, after Operations," when it should be "Glaucoma Fulminans after Cataract Operations with Iridectomy."

Section on Dental and Oral Surgery.

"The Origin of Pus," by W. H. Atkinson.

Series of Lantern Exhibits in Embryology, by W. Xavier Sudduth, M.D., DD.S., F.R.M.S., of Philadelphia.

The lantern used will be the new and improved lantern of the McIntosh Battery and Optical Co., and will be operated by Dr. McIntosh, of Chicago.

"Teeth of Pregnant Women," by John Marshall, of Chicago.

PROPOSED RULES FOR SECTIONS.

The following rules are recommended for the government of the Sections:

1. Reading of papers limited to twenty minutes each.

2. Discussion limited to five minutes for each speaker.

3. All who take part in the discussions do so with the *express agreement* that they will write out the substance of their remarks for publication, before leaving the room.

CHANGES IN PROGRAMME.

We have been requested by Dr. H. R. Storer, Chairman of the Committee of Arrangements, to publish the following alterations in General Programme:

First Day. Under Announcements, insert "that Rush Monument Committee meets at Music Hall immediately after adjournment, and that the Sections and Judicial Council meet at 2 P.M., at the Casino," etc.

Alter to "Addresses of Welcome by His Excellency, Hon. Herbert W. Ladd, Governor of Rhode Island," etc.

Second Day. Prayer. R.R. Thos. M. Clark (Episc.), Bishop of Rhode Island.

After Dr. Pepper's Address, insert "Report of Rush Monument Committee."

Third Day. Prayer. Rev. James Coyle (R. C.) of Newport; R.R. Dr. Harkins, Bishop of Providence, being prevented by duties attending the consecration of the Cathedral of the diocese.

Strike out Report of Rush Monument Committee.

Fourth Day. Meeting at 10, instead of 9.

"Prayer. Rev. D. A. Jordan (M. E.), Presiding Elder, Providence District, N. E. Southern Conference."

RAILROAD ARRANGEMENTS FROM NEW YORK.

Dr. Liston H. Montgomery, of Chicago, a member of the Committee of Arrangements, informs us that the Old Colony Railroad will sell tickets from New York and all points on their line at a fare and a third (certificate plan) for the round trip, thus enabling those who go from points west of Buffalo, Niagara Falls, Pittsburgh and Wheeling, after they purchase their tickets to New York, to avail themselves of this reduction.

The round trip fare by Fall River Boat Line is \$4.50, by rail, Short Line, \$7.65.

"THE AMERICAN MEDICAL ASSOCIATION ANNUAL."

We are requested by the Chairman of the Committee of Arrangements, Dr. H. R. Storer, to

state that he peremptorily refused to give any aid or information to the outside party referred to in the "Special Notice" published in the editorial department of THE JOURNAL on June 1.

SOCIETY PROCEEDINGS.

American Laryngological Association.

Eleventh Annual Congress, held in Washington, D. C., May 30, 31, and June 1, 1889.

FIRST DAY.—MORNING SESSION.

The Association was called to order by the President, DR. ETHELBERG CARROLL MORGAN, of Washington, who delivered the

PRESIDENTIAL ADDRESS.

He expressed the profound pleasure which he experienced in welcoming the Association to the National Capital, the home of the scientific libraries, laboratories and museums, fostered and encouraged by a liberal government. The Association had wisely followed in the wake of numerous other scientific bodies, which make pilgrimages to our city and exert a healthy influence toward popularizing their special fields of scientific investigation. The noble work of this Association during its eleven years of existence has resulted in placing laryngology upon a substantial basis and in demonstrating its truths and benefits alike to the profession and to suffering humanity. The outlook for laryngology was never brighter than at present.

The tenth volume of the "Transactions" is now in press, and in addition to the papers read at the last meeting of the Association, contains a table of contents of all the papers read to the Association since its organization.

An important amendment to the constitution, increasing the limit of active fellowship, comes up at this meeting. The present limit is fifty, and there are at present no vacancies.

Our library now contains nearly 900 separate titles. The librarian thinks that the collection would be more accessible if in charge of the Surgeon-General's office, and recommends its donation to that library. The Association has lost no members by death since the last meeting.

After some suggestions in regard to the social features of the annual meetings, the president closed by reiterating the assurance of his heartfelt appreciation of the good-will and friendship which had influenced the Association in selecting him as the president of this distinguished body.

DR. E. CARROLL MORGAN, of Washington, D. C., reported a case of

REMOVAL OF A SUPERNUMERARY TONSIL.

The patient, a male, æt. 26 years, vigorous and

otherwise healthy, came under observation Sept. 7, 1886, with what he feared was malignant disease of the pharynx. The growth was first discovered four years previous. It had occasioned considerable pain, especially after smoking. During the past two months the growth had rapidly increased in size and the pain had become of a shooting character, extending to the ears, larynx and top of the head. Examination revealed a pendant tumor between the right palatine folds near the uvula and protruding beyond their borders half an inch. The tumor was as large as a small almond. Its color, as well as that of the pillars, was a dusky red. Slight engorgement of the cervical glands appeared to exist. The patient's mother had died of cancer of the breast, and he felt convinced that the growth was malignant. Local and general treatment having no effect, the tumor was excised and the raw surface cauterized with the hot iron. In ten days the wound had healed. The patient was recently examined and there had been no recurrence, now four years after the operation. The specimen removed was examined by Dr. W. M. Gray, microscopist to the Army Medical Museum, who stated that its structure was identical with that of a faucial tonsil which had undergone hypertrophy. The location and microscopic characters of this tumor, as well as the history of the patient prior and subsequent to the operation, proves that this was a hypertrophied accessory or supernumerary tonsil, an exceedingly rare anomaly. A search of the literature had revealed only two other cases of a similar character, reported by Jurasz in 1885. In the first case the tumor was as large as a hen's egg, and was found to spring from the lower anterior portion of the right posterior pillar, by a small and short pedicle. It was removed and found, on microscopical examination, to present the structure of a hypertrophied tonsil. In the second case the tumor was of the size of a hazelnut, and attached below the right tubal prominence. The microscope revealed a structure similar to that of the faucial tonsil.

Conclusions.—1. The lymphoid follicles of the soft palate and pharynx are liable to be aggregated, resembling in arrangement the faucial tonsil. 2. The condition is exceedingly rare, since, excepting the so-called "pharyngeal tonsil," the author has found but one case reported. 3. These lymphoid follicles are also liable to hypertrophy. 4. Such hypertrophies probably occur oftener than is generally supposed. 5. The indications for operative interference in this condition are identical with those for the faucial tonsil.

DR. D. BRYSON DELAVAN, of New York, thought that possibly cases of supernumerary tonsil were not so infrequent as was commonly supposed. Pedunculated tumors of the tonsil which, on examination, show a fibroid structure, are not rare, and it may be that there are degen-

erated supernumerary tonsils; just as the tonsil may, from long continued inflammation, become the seat of fibroid change.

DR. GEORGE W. MAJOR, of Montreal, read a paper on

THE RELATION BETWEEN FACIAL ERYSIPELAS AND ERYTHEMA ON THE ONE HAND, AND INTRA-NASAL PRESSURE ON THE OTHER.

The following cases were cited to show that facial erysipelas may be produced by nasal conditions, particularly when they are productive of pressure:

Case 1.—A girl aged 12 years came under my observation in March, 1884, for the treatment of nasal catarrh. There was a general hypertrophic condition, with pressure of the middle turbinated body of one side against the septum. On the cheek bone of the same side there was a red patch of erythema, which had existed for five months. Treatment of the nasal condition by scarification, puncture and galvano-cautery was followed by disappearance of the erythematous rash, and it has not returned.

Case 2.—A child 4 years of age was seen in February, 1885, suffering with facial erysipelas, commencing on the bridge of the nose and extending to the cheeks. It had already lasted five days, and was not disposed to yield to treatment. Both nostrils were occluded by swelling. All treatment directed to the relief of the erysipelas was suspended, and attention directed to the relief of the nasal condition. In twenty-four hours the erysipelas had disappeared.

Case 3.—In the winter of 1884, a boy, aged 12 years, the subject of recurring attacks of erysipelas, was seen with an attack involving the nose and cheeks. Nasal injections alone were used, and the erysipelas disappeared in thirty-six hours.

Case 4.—February, 1889, a female, aged 56, presented herself with an erythematous patch on the left cheek. This had lasted four months. There was swelling of the left turbinated bone, which pressed against the septum. Under treatment of the nose the erythema disappeared in the course of a week.

Six other cases were alluded to, in which the same condition was seen.

DR. J. O. ROE, of Rochester, had seen a number of cases of erythematous rash due to the nasal trouble. A case recently seen was that of a girl, 23 years of age. There was a very red erythematous patch on the face associated with blebs. She had been treated by various physicians without benefit. In both nares the middle turbinated bodies pressed firmly against the septum. This was relieved and there was immediately a subsidence of the erythematous trouble. He, however, could not admit that erysipelas is due *per se* to the intra-nasal trouble. He held that erysipelas is an infectious disease

due to a distinct germ. The presence of erosions in the nasal cavity would render the patient more liable to become infected.

DR. J. N. MACKENZIE, of Baltimore, said that the relation between erythema of the nose and face and intra-nasal trouble had been recognized centuries ago in the time of Willis and by Sylvius. He himself had seen many cases of this kind, but he had never seen true erysipelas due to this cause. So-called facial erysipelas seems to be comparable to an accentuation of the act of blushing—a sort of chronic blush.

DR. WILLIAM H. DALY, of Pittsburgh, was not a believer in the theory of intra-nasal pressure. The evils referred to pressure are really due to intra-nasal turgescence. The condition of erythema is nothing more than a condition of hypernutrition due to a permanently dilated and enlarged blood supply. He believed that the term chronic facial erysipelas is a misnomer.

DR. F. I. KNIGHT, of Boston, remarked that in these cases of erythema of the nose and face he always looked for nævus and very often found it. Where the trouble has been relieved, the affection of the skin has disappeared.

DR. D. BRYSON DELAVAN, had seen several of these cases, and in three or four the erysipelatous attacks have been severe. One case, a girl of 17 years, had recurrent attacks of severe erysipelatous swelling from the alæ of the nose extending over the cheek. These recurred at intervals of two or three weeks. There was marked turgescence of the nasal mucous membrane. This was treated topically, and with the subsidence of the catarrhal trouble the attacks of erysipelas disappeared.

DR. SAMUEL W. LANGMAID, of Boston, then reported

A CASE OF ACUTE MULTIPLE ADENITIS (SEPTIC?)
CEDEMA OF THE LARYNX WITH SPONTANEOUS CURE.

He was called to see a lady, æt. 40, who had been sick for seven days, under the care of an irregular practitioner. The patient was found restless, with an anxious expression, breathing with difficulty, and with a dry, croupy cough. There was no lividity of the face, but it was stated that during the preceding twenty-four hours there had been danger of strangulation. The submaxillary glands, as well as those in the region of the neck, were much swollen. Temperature 99°; voice fairly loud and clear; no enlargement of the tonsils; nothing unusual in the naso-pharynx. With the laryngoscope a tumor, apparently as large as a filbert, was seen occupying the posterior arytenoid space. The anterior third of the vocal cord could be seen approximated and scarcely moving during respiration. He learned that the throat had not been examined until four days after the commencement of the attack. As

the patient was breathing fairly well it was decided to do nothing. If necessary, the tumor in the larynx was to be incised. A few hours later something was felt to break in the throat, and a free mucoid discharge took place. Three hours later, nothing could be seen but the erect epiglottis, with muco-purulent matter welling up. There was a continued discharge, but the relief to breathing was not complete. There had been, also, the discharge of half an ounce of pus. The discharge continued for several days, and the patient gradually recovered.

It was thought that the case was in all probability due to diphtheria, the evidences of which had passed away when the author examined the throat. The patient stated that at the commencement of the illness, the throat had been sore, and that on one side she had noticed red spots on which there had been a white covering.

DR. WM. C. GLASGOW, of St. Louis, read a paper on

AN ŒDEMATOUS FORM OF DISEASE OF THE UPPER AIR-PASSAGES.

He described an œdematous form of disease which had been epidemic around St. Louis for some two years. During the existence of this affection there has been a disturbance of the ordinary catarrhal troubles. In all cases of this disease there is found a pale, œdematous condition of the fauces. This is a solid œdema. A peculiar glistening appearance is at times very marked. In the majority of cases the soft palate is the seat of œdema. At times the nasal mucous membrane is found in the same condition. The epiglottis and different portions of the larynx may be involved. In some cases the true cords are markedly œdematous. A swollen condition of the veins, particularly the palatine veins, is present. This sometimes causes purpura-looking spots, and the mucous membrane appears mottled. In two cases these purpura-looking spots had been seen in the trachea. In one case enlarged veins were seen on the true cord. In some cases ulceration occurs. In some cases, in addition to œdema, there were patches of exudation in different parts of the throat. These when removed leave a bleeding surface. The symptoms of the disease and the appearance of the throat preclude the diagnosis of diphtheria. In six cases spots of mycosis were seen. Glandular enlargement of the neck is quite frequent. In two cases suppuration occurred.

The symptoms are constitutional and local. The affection occurs suddenly in persons of previous good health. There is languor, weakness, and general pains throughout the body. Headache is present, usually frontal, sometimes occipital. In many cases it is simply a dull heavy feeling, in others it is an intense violent throbbing pain. Pain in the back in the region of the

sacrum is a characteristic symptom. Fever is present in varying degree. In the exudative cases, the disease commences with chill followed by fever, and the temperature may reach 105°. This soon passes off, and we have a subfebrile condition remaining, probably with a temperature of 101°. This continues a short time, and then there is a return to the normal temperature. When there is simple œdema, the temperature scarcely ever rises above 101° to 102°. This remains for only twelve hours, and during the remainder of the attack the temperature is normal. The pulse is always rapid, soft, and compressible; there has been no exception to this noted. The pulse ranges between 90 and 110 per minute. Profuse sweating is often present, especially during the night. It may be localized.

AFTERNOON SESSION.

DR. JOHN N. MACKENZIE read a paper on
SOME POINTS IN THE PATHOLOGY AND TREATMENT OF DISEASES OF THE NASAL PHARYNX.

The following conclusions were presented :

1. The nasal pharynx is in quite a large proportion of individuals exceedingly sensitive to reflex-producing stimulation.

2. The areas chiefly involved are the posterior portions of the turbinated erectile tissue, and various points along the upper and posterior portions of the nasal pharynx.

3. In consequence of this extreme sensitiveness, a local pathological process which in many persons would give rise to no reflex neuro-vascular changes may awaken a host of neurotic phenomena referable not only to the region primarily involved, but also to others and even remote organs of the body. These may include cough, asthma, and various neuralgic affections; or the local structural lesion may be the starting-point of various sympathetic affections of the respiratory tract.

4. That these classes of naso-pharyngeal neuroses are explicable on the same general principles laid down in the article on neuroses of the nose, and the pathology of the nasal and post-nasal affections is, therefore, one and the same.

5. That the treatment should be carried out according to the general directions laid down in the article just mentioned.

6. That when morbid processes originate in the pharyngeal tonsil, attention should not be directed to the bursa alone, but an endeavor should be made to extirpate the tonsil as far as possible in its entirety.

7. That while a favorable prognosis cannot be safely predicted by the treatment of the bursa alone, extirpation of the pharyngeal tonsil often affords a most favorable prospect in long-standing cases of post-nasal trouble.

DR. D. BRYSON DELAVAN then presented some

OBSERVATIONS UPON THE CONDITION KNOWN AS
ADENOID HYPERTROPHY AT THE VAULT OF
THE PHARYNX, AND THE METHODS
USED FOR ITS REMOVAL.

A case was described in which with each acute attack of catarrhal trouble there would be enlargement of the adenoid tissue of the vault of the pharynx, forming a large tumor. When the attack passed away the hypertrophy disappeared. The author then referred to the methods of operation and the accidents which might occur. As the operation was attended with considerable pain he suggested the employment of anesthesia. He had in a number of cases employed chloroform with satisfactory results, the object being to avoid the profuse mucoid secretion which is apt to follow the use of ether. Where chloroform is used the operation is performed with the patient on his back.

DR. F. H. HOOPER, of Boston, reported a case of a young lady who came to him with acute coryza and in whom he found a large-sized adenoid of the vault. After the attack subsided, the adenoid almost entirely disappeared. In order to avoid error, the post-nasal probe should always be used. With it conditions not apparent to the eye may be recognized. He had never seen serious hemorrhage follow operations for the removal of the tissue. In operating he first removes all that is possible with the post-nasal forceps and completes the removal with the finger-nail. He had never used chloroform. The amount of secretion after the use of chloroform varies very much in different cases.

DR. HARRISON ALLEN, of Philadelphia, advocated the use of the finger as a means of detecting these post-nasal affections. To examine the case thoroughly requires the use of an anæsthetic. In the treatment of adenoid hypertrophy, it is better to remove all the diseased tissue at one sitting under ether than to remove it in portions at different times.

DR. J. C. MCLHALL held that for practical purposes the pathology of the pharyngeal tonsil was exactly the same as that of the faucial tonsil. In operating, he had applied cocaine thoroughly to the pharyngeal wall and soft palate to avoid the disagreeable sensation caused by the scraping of the forceps against the healthy pharyngeal wall, and had succeeded very well.

DR. F. I. KNIGHT related a case of acute hypertrophy of the faucial tonsil in which the surgeon performed tracheotomy preparatory to removing the tumor. When he came to operate he found that the growth had disappeared.

DR. WILLIAM E. CASSELBERRY, of Chicago, referred to the importance of thoroughly eradicating these growths. In two cases in which portions of the mass had been left, the reflex symptoms, while greatly lessened, continued to recur. In two cases he had attempted to use the mirror

during operation. To do this he pulled the soft palate forward by two rubber bands, passing through each nostril. In one case he succeeded to a certain extent, but in the other failed. This procedure, however, greatly facilitated the operation. In order to prevent the passage of blood into the larynx he was in the habit of bending the head forward at intervals in order to allow the escape of the blood.

DR. J. N. MACKENZIE, as a rule, operates without anæsthesia, removing a portion of the mass every day, or every other day, continuing the operation for a week or ten days. He had seen very little pain from the operation. There is one point in regard to the nature of this so-called adenoid. He had examined a number of these growths under the microscope and they do not differ from papillomatous growths. There is also in addition a true adenoid growth; this is more difficult of removal than the former.

DR. F. H. HOOPER read a paper on

EXPERIMENTAL METHODS OF STUDYING THE AC-
TIONS OF THE INTRINSIC MUSCLES
OF THE LARYNX.

He exhibited the apparatus which he had employed in studying the effect of stimulation upon the internal thyro-arytenoid, the lateral crico-arytenoid, and posterior crico-arytenoid muscles. The larynx of a dog is quickly excised, the mucous membrane removed, and the muscles subjected to electrical stimulation.

The local symptoms vary with the part of the throat invaded. Sometimes they are prominent, sometimes they are wanting. Hæmorrhages are common, are usually slight, but recur frequently.

This is a constitutional disease, due, the author believes, to some change in the blood; exactly what, he was unprepared to say, but probably due to microorganisms. He thought that the disease described was nothing more than influenza, the same influenza which has been described so often, particularly by Graves. The disease has not been limited to the Mississippi Valley, for the speaker had seen cases of it from all parts of the country.

The treatment is very simple. The system must be saturated with benzoate of sodium. Under this remedy the affection subsides in a few days or hours. If left to itself it may continue for weeks or even months.

DR. W. H. DALY, of Pittsburgh, had seen a number of cases similar to those described. He did not consider the condition as one of œdema, but rather as a subacute inflammatory condition of the mucous membrane. There was a sufficient number of these cases which had thin and superficial diphtheritic patches in various parts of the fauces to warrant him in considering the disease of a diphtheroid character. This view was confirmed by the subsequent occurrence of glandular enlargement in nearly all the cases.

DR. J. C. MULHALL, of St. Louis, confirmed the statements of Dr. Glasgow from his own experience with the disease in St. Louis, and reported a case in which the affection had recurred three times.

DR. S. H. CHAPMAN, of New Haven, had seen cases similar to those reported, but agreed with Dr. Daly that they are rather of a diphtheritic character. In one case the disease attacked a child of 17 months. In the same family was a boy 9 years of age with well-marked diphtheria. The first thing noted in the case of the child was a dense swelling of the submaxillary gland. There was great prostration and some fever, 100° – 102° . The swelling increased until it extended from the jaw to the clavicle. There was hoarseness and difficulty of breathing, which daily increased. By the seventh day it had increased so much that deep incisions were made into the gland, but no pus was found. A tube was then inserted into the larynx and allowed to remain four days. The child during this time was kept alive by rectal alimentation. At the end of *thirteen* days the swelling began to diminish. The knife was again used and a quantity of pus discharged. The child recovered.

DR. C. E. SAJOURS, of Philadelphia, referred to a case of this disease which occurred in a young man living on a farm in New Jersey, twenty miles from any neighbors, and who had not been exposed to diphtheria. The throat presented small white patches not resembling the yellowish leathery membrane seen in diphtheria. Slight oedema of the soft palate was also present. The temperature was high throughout the entire course of the disease. There was incessant pain in the back and in one limb. After trying a number of remedies, he was placed upon benzoate of sodium.

DR. W. C. GLASGOW, of St. Louis, remarked that he had at first regarded these cases as diphtheritic. In these cases the membrane is adherent; it can be torn away, but a bleeding spot is left. Applications made it worse. If left to itself, it gradually grows thinner and thinner until it resembles a white pearly patch. Diphtheritic membrane does not pursue such a course. The glandular enlargements always occur, even when there is no exudation. He did not think that any one would assert that this oedema was diphtheria.

DR. W. H. DALY, of Pittsburgh, made some remarks on

THE INTIMATE RELATIONS OF CHRONIC DISEASES OF THE UPPER AIR TRACT AND NEURASTHENIA.

His experience had led him to believe that there was an intimate relation between conditions of the intra-nasal cavities and neurasthenia in some of its forms. This view was based upon the study of twenty-five cases. In these cases removal of the nasal trouble was followed by relief of the neurasthenic condition, no special treatment being directed to the general condition.

DR. J. O. ROE, of Rochester, said that most of the members had seen many such cases, and they illustrate the effect that a constant local irritation will have upon the system. A constant nagging of a local irritant will sooner or later produce a depressed condition of the system.

DR. F. W. HINKEL, of Buffalo, remarked that before we could admit that neurasthenic conditions could be the result of any nasal lesion as the sole cause, a careful analysis of all the constituent conditions would be required.

DR. S. W. LANGMAID, of Boston, thought that often the nasal trouble was the result of the neurasthenia. It often happens that operative interference fails to relieve the nasal condition because the neurasthenia is not cured.

DR. C. E. SAJOURS, of Philadelphia, was inclined to support rather vigorously the view of Dr. Daly. In a number of cases he had observed that there were fluctuations in the nervous condition according as the local disease improved or became worse. In one case of neurasthenia associated with deviated septum, correction of the displacement was followed by improvement in the nervous condition. The operation, however, failed to be permanent, and with a return of the deviation the neurasthenic condition recurred, to again disappear with a more thorough operation upon the septum.

DR. F. I. KNIGHT then read a paper on

DYSPHONIA SPASTICA.

He briefly reported the four cases of this affection which he had seen in the last seven years. He regarded the condition as rare; there is probably a spasmodic action of the muscles of phonation, or respiration, or both, giving rise to a high-pitched, jerking voice. The prognosis is unfavorable. The object of the paper was to elicit reports of other cases.

DR. G. W. MAJOR had seen one case of aphonia spastica and two cases of dysphonia spastica. In none of the cases was benefit obtained by treatment.

DR. S. W. LANGMAID had reported one case in which treatment was unsuccessful. The patient, when he had to use his voice, prescribed for himself a little whiskey, and this answered temporarily. There seems to be no change in the voice since the affection first came on, fifteen years ago.

DR. DELAVAN said that in one case coming under his observation the patient was able to talk tolerably well after fortifying himself with a stimulant. This patient seemed to improve under local treatment to the larynx and vocal training, but the treatment could not be continued.

DR. C. E. BEAN, of St. Paul, had seen one case two years ago. Various methods of treatment had been employed without benefit. The voice is now the same as at the commencement.

DR. RUFUS P. LINCOLN, of New York, read a paper on

RECURRENT LARYNGEAL GROWTH.

The patient had come under the care of the late Dr. Elsberg, twenty-four years ago. Dr. Elsberg first operated by the intro-laryngeal method, but could not remove the growth. Twenty-two years ago he did laryngotomy and removed the growth. The microscopical examination made at that time was unsatisfactory. There was no further trouble until a short time ago when the growth recurred. Dr. Lincoln recently removed the tumor, which on microscopical examination proved to be a papilloma.

(To be concluded.)

Connecticut State Medical Society.

Ninety-eighth Annual Meeting held in Hartford, Conn., May 22 and 23, 1889.

FIRST DAY.

DR. GEO. L. PORTER, the President of the Society, in delivering his Address, made remarks on the present standing of the Society, and agreed with the President of last year, that radical changes should be made in the manner meetings are now held, alternately at New Haven and Hartford.

DR. W. W. KNIGHT, the Treasurer, reported that there was a balance in the treasury of \$277.24.

The election of officers resulted as follows: President, Dr. O. Brown, of Washington; Vice-President, Dr. Melancthon Storrs, of Hartford; Treasurer, Dr. W. W. Knight, of Hartford; Secretary, N. E. Wordin, of Bridgeport; Committee on Matters of Professional Interest, Dr. Henry Fleischner, Dr. C. H. Beach, Dr. F. D. Edgerton; Delegates to the Pharmaceutical Association, of 1890, Dr. C. A. Lindsley, Dr. F. J. Young, Dr. O. J. D. Hughes; Delegates to American Medical Association, Drs. F. H. Wiggins, M. Storrs, M. A. Cremin, R. S. Goodwin, W. Cummings, J. Olmstead, C. N. Alling, E. T. Bradstreet, F. L. Smith and Wm. Winter. Delegates were also appointed to attend the State meetings of Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, New York and New Jersey.

Dr. E. M. Moore, of New York State, was elected an honorary member, and the name of Prof. Wm. H. Welch, of the Johns Hopkins University, was proposed. This, in accordance with a by-law, went over for one year. After transacting other business of minor importance the meeting adjourned.

In the evening the members were received at the residence of Dr. Wainwright.

SECOND DAY.

The meeting was called to order at 9 A.M. The Secretary, Dr. N. E. Worden, reported that there had been 32 new members admitted during the year, and that present membership is 508.

DR. L. B. ALMY, Chairman of the Committee on Matters of Professional Interest, gave the results of papers sent to the doctors in different parts of the State, asking what had been their experiences with antipyrin, antifebrin, phenacetin, sulphonal and saccharin. The drugs had been pretty thoroughly used and generally the results were satisfactory.

DR. P. H. INGALLS of Hartford, read a paper on

UTERINE CANCER.

The author thought no faith was to be put in the hereditary theory. He said that the theory of local origin was fast gaining ground and he would not be surprised if in the future a germ would be isolated as the cause of cancer. The generally accepted causes are age, child-birth and injuries. Thomas says he never knew a woman to have uterine cancer who was never pregnant. Early diagnosis was very important, and if there was any suspicion of cancer the microscope should be used to decide. Surgical interference was the only treatment, except opium for pain and a solution of permanganate potassium for the bad-smelling discharges. Good hygienic surroundings were of course necessary. Operation should be early and thorough. If the disease had extended beyond the uterine tissue it was too late to operate, as it only increased the inflammation. He spoke of the different operations, but preferred vaginal hysterectomy.

DR. J. G. HOLMES, of New Britain, read a paper on

SCARLET FEVER.

This paper was a general review of the disease with the treatment and hygiene.

DR. SETH HILLS read a paper entitled

PHTHISIS PULMONALIS.

The theory of contagion in this disease was spoken of, and the author claimed no one had consumption without taking it from some outside source. The typhoid-fever germ was hunted to its death, while the germ of consumption, that most widespread of all germ diseases, is allowed "to go scot free." The medical profession should take some decisive action. He thought the time was not far distant when the patient with tuberculosis would be isolated from the healthy.

THE PRESIDENT in his address gave greeting to those present and reminded them that they were responsible for the future of the Society. The meeting in Paris for the consideration of phthisis, he thought, was the most important medical event of the past year. At that meeting

it was shown that it was the opinion of most present that consumption was probably contagious. Health was a factor of political economy. Anything to prevent sickness or to alleviate it was an act of statesmanship. The State ought to enact laws to govern the sick and the healthy, so that disease would be reduced to its minimum. The prosperity of the country depends upon the common people, and our country is more dependent upon the health and character of its people than any other. Public health is public wealth. When a laborer is taken sick he becomes a burden to the community. He quoted statistics to prove that the loss to the country by sickness is about \$392,000,000 yearly, and when a pestilence sweeps the country the amount is vastly larger. Boards of Health are now appointed to prevent the spread of disease, and the amount of good they do can be seen by the results that have been obtained in so greatly reducing the number of cases of small-pox. The question of the future is how to prevent disease. This could not be solved by the busy practitioner in the sick-room, but must be done in the laboratory.

DR. G. H. JENKINS read a paper on the *Pollution of Sources of the Supply of Water and Ice.*

Chronic Pachymeningitis Interna was the title of a paper by Dr. J. F. Calef, and a paper on *Fractures* was read by Dr. C. B. Newton.

Philadelphia County Medical Society.

Stated Meeting, April 10, 1889.

THE PRESIDENT, W. W. KEEN, M.D., IN
THE CHAIR.

(*Concluded from page 821.*)

SPECIMENS EXHIBITED.

DR. J. PRICE: Mr. President, I have here a small group of ovarian cysts of mixed character, removed early. The patients were all sufferers. One had been under rest treatment for fourteen months. This one was removed by Dr. Müller, of Germantown. It is a typical example of a parovarian cyst with a large, healthy ovary and slight adhesions. There was a small cystoma of the other ovary. Most of these small cysts occurred in young women. This small dermoid I removed from a patient aged 19. The operation was done four months ago, and she is now pregnant at the second month.

This was a fibroid in the left broad ligament, which had evidently gravitated into this position, and was removed per vaginam.

I have here three specimens of typical extra-uterine pregnancy. This large one was almost of the size of a child's hand. This was a case of Dr. Bernardy's, in which he made a positive diag-

nosis. The placenta and membranes are inside. On the other side there was a hydrosalpinx. This demonstrates the theory of Mr. Tait in regard to the causation of tubal pregnancy, *i.e.*, desquamative salpingitis. In the second place the placenta is in position. All of those specimens have been examined under the microscope, and there is no question as to the diagnosis.

I do not wish to give complete histories of the patients from whom these specimens were removed. In many cases they are very similar. Most of them had been subjected to a great variety of treatment and torture, and had not been benefited. Some made narrow escapes from death. Some were pus tubes, unilateral, or bilateral, some recent, some long standing. In some of the latter it was difficult to say which was the tube and which was the ovary. In a few cases there was abscess of one or both ovaries. In a few cases there existed a small broad ligament cyst. Many of these tubes were enlarged, some being as large as the fundus of the uterus.

I have here a fresh tube removed by Dr. Hoffman. Here is a group of abscesses of the ovaries co-existing with pus tubes. In many of these there were several distinct abscess cavities. If tapping had been resorted to in these cases it would have been necessary to have tapped several cavities.

In this group I have six cases that refused operation from one to five years ago. We are often asked what becomes of the patients who refuse operations. Some die in the hospitals. These cases drifted around among other doctors, and finally returned for operation. Two cases in which I had urged operation, one four months ago, the other six months ago, came to me at midnight, stating that the temperature was 104° and the pulse 140, and requesting an immediate operation. In both I refused to operate until the following day, and both recovered from the operation.

We are often told that the fluid portion of the pus may be absorbed and the patient recover. This may be true in some few cases, but the matter still remains as a source of mischief. These pus tubes are not rarely the cause of psoas abscess. In one case, which I sent to the Pennsylvania Hospital, the psoas abscess was due primarily to pus tube and abscess of the left ovary—demonstrated post-mortem.

This is a very large dermoid. I had picked this case out for operation, five years ago, at that time there was a small tumor behind the uterus. After I saw her five years ago she conceived and bore a child, and suffered some post-puerperal trouble. The existence of a small tumor is unquestionably a common cause of post-puerperal trouble.

The patient from whom this tube was removed was very ill when I was asked to see her by Dr.

Hoffmann, two weeks before the operation. I found her leaking copiously with a rapid thready pulse, and thought that she would die on the table if an operation were attempted. Under treatment her condition was somewhat improved, and the operation performed. I shall open this tube before you. It contains a fluid that looks like pus. This tube contains several sacs. This is an interesting point in connection with the Martin method of dealing with pus tubes by tapping. A single tapping would not reach all of the sacs.

DR. JOSEPH HOFFMAN: I have a word to say in regard to diagnosis in connection with my own specimen. I first saw the patient six weeks ago. She had been under the observation of a gentleman who thought she was pregnant. I found trouble on the right side, but did not discover that on the left side as I did not look for it. I considered the mass on the right side either a complication of the bowel, a pus-tube, or extra-uterine pregnancy. It turned out to be a pus-tube. In the course of a few days the patient developed symptoms of typhoid fever. Previous to this there had been no symptoms of fever and no other symptoms, with the exception of pain in the pelvis. She was suddenly seized with nose-bleed, high fever, and for several days the temperature followed the ordinary course of that of typhoid fever. It was this that placed her in the condition in which Dr. Price found her. The strange point is, that up to this time the woman had never had fever, nor any of the ordinary signs of pus. Nor had there been symptoms of peritonitis. The woman was in a very bad condition at the time of the operation. After the operation the temperature was below normal and she was covered with a cold sweat. She was only kept up by the careful application of heat. During the six days following the operation the highest temperature was 102.4. To-day, the tenth day, it is 98.8. There was universal peritonitis. The omentum was adherent, and no attempt was made to loosen it. This case shows that the statement that the peritonitis from such a cause is local, and not general, is nonsense. The only symptom that I dislike is a small discharge of pus from the drainage tube.

DR. M. PRICE: Large ligatures are useless. The smaller the ligature that will do the work the better. The ligature shown by Dr. Penrose is too large. In my case of removal of the kidney I applied two ligatures, one large and the other small. The large one worked through the back three months after the operation, and there was absolutely no change in it. I believe that in intra-peritoneal operations large ligatures are dangerous.

DR. C. B. PENROSE: The first specimen is a very unusual specimen of a fibroid uterus which has undergone cystic degeneration. I removed it

this morning by abdominal section. There was in the upper part of the tumor a cyst containing three quarts of fluid. This was tapped before the tumor was extracted. In all, five quarts of fluid were contained in the tumor, and the sense of fluctuation was as great as in an ovarian cyst. The cavity of the uterus would hold a quart of fluid, and is separated from the cysts throughout the tumor only by a membrane as thin as peritoneum.

The next specimen is an unusually large hydrosalpinx removed from a woman twenty-five years of age. It contained ten ounces of straw-colored fluid. The cyst wall was thin and transparent.

The third specimen is a hæmato-salpinx removed from a woman aged fifty-three years, with fibroid of the uterus of the size of a child's head. This case illustrates the fact that in many cases of uterine fibroid there exists disease of the tubes and ovaries. This has an important bearing upon the method of treatment employed in these cases. The removal of the ovaries not only stops bleeding and causes shrinkage, but it also takes away diseased and dangerous structures; a result not possible to obtain by means of drugs or electricity.

I have here a ligature removed from a woman who had suffered for twelve months from a sinus and fecal fistula which had followed operation for pyosalpinx, in one of the hospitals of this city. The sinus involved a drainage tube tract. When I operated much of the small intestine was found adherent in the pelvis and at the bottom of the fistulous tract, lying on the sigmoid was this ligature, in immediate contact with the opening into the bowel. This was undoubtedly the cause of the sinus and the fecal fistula. The ligature is unnecessarily thick, and the knots would be likely to render it irritating. The wall of the fistulous tract, as you can see, was formed of well-organized lymph.

The case shows the danger of permitting a drainage tube sinus to run too long without surgical interference. In this case there was, for the first few months, only a purulent discharge, but the walls of the bowel finally became destroyed, and a fecal fistula resulted.

Allegheny County Medical Society.

Special Meeting, March 19, 1880.

WM. F. KNOX, M. D., PRESIDENT, IN THE CHAIR.

DR. DUFF: Two months ago I reported a case of rheumatism, or rather a case of rheumatism associated with eruptions around the joints; at the time I did not understand the case, and could not say what the outcome would be. The rash

was first papillary, then vesicular, following up in the order of the joints attacked. A few days after, I found several large blebs over the shoulder, just such as we have arise after the application of cantharides plaster. As they dried up, the submaxillary glands and cervical glands began to enlarge and continued until suppuration occurred, and discharged large amounts of pus. After suppuration occurred, the young lady improved rapidly. I am still at a loss to account for the condition, and promised that I would give the result of the case.

DR. PAINTER reported a case of

CONGENITAL MALFORMATION OF THE SOFT PALATE.

Mrs. F., æt. 40, a widow eight years, consulted me on account of hoarseness following a cold. Inspecting the pharynx, I found an unique anatomical relation existing between the upper part of the pharynx and the soft palate, of which the patient was ignorant. The free border of the soft palate and the palato-pharyngeus muscle on either side are carried backward and attached to the posterior wall of the pharynx, forming a diaphragm between the superior and middle divisions of the pharynx. In this dividing membrane there are two somewhat circular openings—one one-half inch, and the other one-eighth inch in diameter. These openings are in the median line. The uvula cannot be distinguished. The patient can give no reason for this marked departure from the normal construction, and was ignorant of any irregularity till I asked her to permit a demonstration of her throat to this Society. She supports a family of five by washing. She frequently has a cold in the head, but experiences no difficulty in clearing the nose. She has never had noises in the ears and hears well. The sense of smell and taste are unimpaired, and her voice, save an occasional hoarseness, has never changed. The voice might be described as muffled. Her sleep is undisturbed. At least two of her children have throats normal in construction. She has had typhoid fever, and believes she had diphtheria when a child. As I demonstrate the case, it will be observed that she is well developed generally and in good health. In the absence of any ulcerative process, I conclude the case to be one of congenital malformation. The case has two interesting points, viz: First, this malformation is uncommon; and, secondly, the absence of symptoms such as one would think should follow such abnormality.

DR. HUSELTON reported a case of

COMPOUND PUNCTURED FRACTURE OF THE SKULL, produced by the calk of a horse's shoe. John T., æt 38, a farmer, was brought into the Allegheny General Hospital on the evening of January 26th with a history of "fractured skull." He was conscious, talked rationally, pupils equal,

no paralysis, and a full, slow pulse. The history, as given by himself, is as follows: He was riding in a "buckboard," leading a spirited horse by means of an ordinary halter. The horse, becoming frightened at a passing railway train, jumped upon the "buckboard," knocking the patient to the ground. He tried to rise, still holding the strap, when the horse reared and came down, his hoof striking the patient on the head, rendering him unconscious. He did not regain consciousness for about one hour after the injury, when he walked into the hospital supported by a friend.

An examination revealed a depressed, punctured fracture of the skull, situated in the frontal bone, two inches above the right eye. The fracture was shaped like, and about the size of a large almond, and very much depressed. A sero-sanguinolent fluid, supposed to be subarachnoid, escaped from the wound, but we were unable to find an opening in the dura mater. This fluid flowed freely as long as the head was resting on the occiput, but on turning it to either side it ceased. I trephined, removing the button from the lower portion of the wound. A number of fragments, principally from the inner table, were removed and the depressed bone elevated into position. There was no hemorrhage from the interior. The wound was flushed with a solution of bichloride mercury (1:4000). A few strands of silk were placed in the opening and brought out at the lower portion of the wound for drainage. The edges were brought together by silk sutures, and the operation completed by an antiseptic dressing. On the morning of the 27th his temperature was 100.4°, but gradually and continually dropped to 98.4° on the 29th, and remained normal from this time on. The dressings were removed on the 30th, four days after the operation. The wound had closed by primary union, and without a drop of pus or discharge of any character. The stitches and silk for drainage were removed on this occasion, and the head was redressed, observing the same antiseptic precautions as at first. These dressings were removed on February 4th; and as every part of the original injury was healed, an ordinary nightcap bandage was applied and the patient was permitted to get up on the next day, February 5th.

The case progressed without an untoward symptom of any kind. The patient was anxious to go home on the tenth day after the operation, but was kept in the hospital as a precautionary measure until February 15, when he was discharged cured, and the opening in the skull was apparently being rapidly closed by a bony deposit. His treatment was practically nil. The diet was liquid for the first few days. A mercurial at the outset was all he had in the way of medication.

DR. BUCHANAN: I would like to say a few

words on the subject of trephining. I think that Dr. Huselton had very distinct indications for his operation, and it certainly was very successful. I think there are one or two points on the subject of trephining that may be dwelt upon. The principal one is that the indications for trephining have entirely changed in the last few years. Formerly, there was a very great difference made between simple and compound fractures. Compound fractures were recommended to be trephined that would not have been considered proper subjects for trephining had they been simple. The presence of a simple depressed fracture, if the depression is slight, it is impossible to make out. A case of depressed fracture occurred in my practice a week ago, in which it would have been impossible for any one to make out the depression by external examination. On the following evening, when symptoms of compression came on, I opened the scalp and found the depression, removed a button of bone, elevated it, removed a clot of blood from beneath the bone, and put on a dressing. The patient afterward had no elevation of temperature, commenced to improve immediately, and is now practically well. The second point that I would call attention to is that the secondary results of depressed fractures are very much better appreciated now than heretofore. The deficiencies in intellect and epilepsies justify more frequent resort to the trephine and elevator in simple fractures of the skull. A case may recover and pass outside of the surgeon's sight, but still be a bad result; six months, a year, or several years after, there may be a chronic inflammation of the membranes of the brain or some damage done to the brain by plastic effusion, which will result in epilepsy or other troubles. I would therefore think that Dr. Huselton, even if there had been no compound nature in this fracture, would have been perfectly justified in elevating it, and I would go even so far as to say that when a fracture of the skull is suspected, if there is even a suspicion of depression, an exploratory operation through the scalp should be undertaken, because if there is no depression, such an operation would not hurt the patient a particle, and if there is a depression, it is exceedingly important to know it and act accordingly.

DR. MUNN: In connection with Dr. Buchanan's remarks on trephining depressed fractures, I will take the opportunity to relate a case which I met in my practice a year ago in April. A man was thrown out of a wagon by a runaway horse, and on being picked up a depressed fracture was discovered on the upper posterior corner of the right parietal bone. He was taken to his home, and there the propriety of an operation was spoken of, but it was declined by the friends of the patient. He passed out of my hands, went under the care of a homeopathic physician, and eventually recovered after remaining unconscious

for seven days; he had hemorrhage from the nose and the ear. Now, after the lapse of eleven months, he presents a decidedly marked depression in the region of the injury, has double vision, slight paralysis of the right arm, slight paralysis of the right leg, has some aphasia, and a slight paralysis of the left side of the trunk. I think the case to-day presents every indication for operation, but the operation was not performed at the time it should have been. Since the injury, he has had two epileptic seizures, nothing of the kind ever having occurred to him before.

DR. HUSELTON: I endorse everything that has been said by Dr. Buchanan and Dr. Munn. I would also add, I think we are too apt to overlook the importance of a fracture of the skull; under modern antiseptic treatment, I think trephining a comparatively safe operation, and in every case I think that where there is reason to suspect a depressed fracture of the skull, the trephine is a proper precautionary measure to be resorted to.

DR. W. P. MUNN presented a specimen, obtained from a cadaver of unknown history, of

ENTIRE ABSENCE OF THE INNOMINATE ARTERY.

At its place of origin the two common carotids arise together, then the left subclavian is given off, and last arises the right subclavian, which passes toward the right, behind the three other vessels.

DR. BUCHANAN: I have a former patient present whom I wish to exhibit. His case I reported to the Society three or four months since. He is a man whose patella I wired. I have not before been able to present him to the Society; I wished to present him at that time, but as I explained, he got out of my reach. I met him on the street sometime ago, and found that he had a very good result, and I thought I would show him to the Society. He was away from his laboring work just eight weeks.

(Patient exhibited.) You will observe that there is no separation whatever to be discovered between the fragments, and the joint movements are perfect. The limb is, to all appearances, as good as its mate.

DR. MURDOCH: Dr. Buchanan is to be congratulated on the result of this case. So far as can be told by an examination of this man's leg, the union is perfect; there seems to be a bony union between the fragments. I say seems to be, because I do not believe it is so; I very much doubt if bony union ever takes place in a fracture of the patella owing to the fact that many specimens have been thought to be bony, but when examined after death and the bones subjected to a process of boiling, it has been found the union was only fibrous after all. But if it is fibrous, it is just as good as if it were bony and just as useful, because there is no separation of the frag-

ments, and by scarcely any other treatment could the two fragments be brought into such close apposition; but anybody who knows the difficulty of treating fracture of the patella knows how difficult it is to keep them in apposition, and that if they are not kept so, the patient is maimed for life. The only objection to this operation that can be raised is the danger of it, but under antiseptic precautions, where they are thoroughly carried out, it is probable that the danger will be but little; but it is a melancholy fact that, notwithstanding the perfection to which antiseptic dressings and surgery have been brought, this operation, even in the hands of the best surgeons, is frequently disastrous, that is the cutting down on the knee-joint, freshening the edges of the bony surface and wiring them together. When I was in New York a year ago last spring, Dr. Sands told me of two cases that he had known where the patient had suffered amputation and had eventually died, where this operation was attempted; and only about a month ago, Dr. Stimson, at a meeting of the Academy of Medicine, in New York, stated that, during the past summer he had known three cases where an operation had been done in New York, and the patients had in all three cases suffered amputation afterward, so that even in the hands of the best surgeons, and with the greatest care taken, it is a dangerous operation, and surgeons have been endeavoring to find one that is less dangerous, that will accomplish the desired result; whether they will succeed or not remains to be seen. About three or four weeks ago Dr. Stimson, after making the remarks I have stated, exhibited five cases where he had tied the patella together subcutaneously, and the procedure seemed to me so simple and so likely to be successful that I think it should be tried, and if it succeeds, it will be much simpler than this operation, and, I believe, safer. The operation is so simple, that I will just show it here on the blackboard, if I can. (Drawing made by the doctor on the blackboard, exhibiting the method of operating.) I tried this last Saturday on an old lady, 60 years of age. I am not able to do what Dr. Buchanan has done, bring my patient here, and perhaps I never shall be able to do so. The patient is perfectly comfortable, and so far as anybody can tell, after this short treatment, bids fair to have a good result. I do not bring this up to criticise Dr. Buchanan. I am very glad to have had an opportunity to see Dr. Buchanan's case, the first one, I believe, that has been operated on in our county.

DR. HUSELTON: I want to congratulate Dr. Buchanan on the successful issue of his case. I had the pleasure of being present when he operated, and am glad to say that I think the operation was very carefully and skilfully performed. At the same time, I do not believe the operation will ever become a popular one; I think that op-

ening so large a joint as the knee-joint is too hazardous, and attended with too much danger, particularly when we are having very good results by the old method. I have had several cases, at least three or four in my practice, the last one occurring about two years ago, treated by the old method, and the result every thing that could be desired. I did claim the union was bony; however, I think this is not the case, but if ligamentous or fibrous, it is almost impossible to detect the fact. I exhibited the case to at least one person here, and would be glad to present the case to the Society at some future time for their inspection.

DR. BUCHANAN: I am very glad Dr. Murdoch presented this new method of treatment. I considered that method shortly after I had done this operation. It was then first brought to my notice. It occurred to me that this certainly is a much safer operation than the open method, but it is open to two theoretical objections, whether they are real objections, time alone will tell. The first is that it will probably in a great many cases, if not the majority, be impossible to approximate the fragments exactly by this method. I should think that the anterior borders of the patella, by this method, would be tilted a little backward, and that would keep the surfaces from coming together. In wiring a bone, it is sometimes a difficult matter to get the surfaces exactly apposed, even when you have everything open before you and are able to handle the parts, and of course it is very much more difficult when you are doing it subcutaneously. And the second objection that I would suppose to exist in regard to this method is, that the torn fragments of the capsule of the joint float in between the fragments. I believe it has been proposed to pass a needle in and hook these out from between the fragments. At all events I should imagine from the case of this man, at least, that it would be very difficult to get these shreds from between the broken bones, and it is said by a number of good surgeons (Prof. Macewen was the first, I believe, to state it), that this is a chief cause of non-union, or rather of the failure of bony union in this fracture. In regard to Dr. Huselton's results, I think he is to be congratulated. I don't think that the result which he has mentioned is otherwise than exceptional in these cases by the non-operative methods of treatment.

AMERICAN CLIMATOLOGICAL ASSOCIATION.—The Sixth Annual Meeting of this Association will be held in the Boston Medical Library Association Hall, 17 Boylston Place, Boston, on June 24 and 25, under the presidency of Dr. Vincent Y. Bowditch, of Boston. The programme contains a large number of papers by eminent physicians.

FOREIGN CORRESPONDENCE.

LETTER FROM PARIS.

(FROM OUR SPECIAL CORRESPONDENT.)

Dr. Worms on Diabetes—Prof. Ollier on the Advantages of the Resection of the Hip-joint in Cases of Suppurative Coxalgia—Dr. Larat on the Treatment of Intestinal Occlusion by Electricity—Dr. Gaucher, of Algiers, on Abortive Treatment for Whitlow—Some Hints on Prescribing Hydrochlorate of Cocaine.

Dr. Worms lately read a note at the Academy of Medicine in which he communicated the result of his long and patient researches on diabetes in a clinical and therapeutic point of view. According to the author diabetes is very often a malady of slow evolution and of long duration. He thinks that none of the existing theories on the pathogeny of diabetes is satisfactory. Moreover, many of the symptoms, such as polyuria, emaciation, thirst, dental caries, which are looked upon as essential symptoms, are often found wanting. In a clinical point of view, the toxic or accidental glycosurias being put aside, the distinction between chronic glycosuria and diabetes mellitus is not justified. As regards the treatment the principal object of the physician should be to maintain in the highest degree the vital energy and integrity of the digestive functions. This result is obtained by the application of the diet and regimen instituted by Bouchardat. Dr. Worms thinks, however, that the gluten bread may be suppressed, and that the patient be allowed to eat ordinary bread in small quantity. Saccharin, which has been proposed as a substitute for sugar for the use of diabetic subjects, appeared to Dr. Worms to cause disgust after a time and to act injuriously on the digestive functions, which it is of the highest importance to preserve intact. As regards drugs, it is the sulphate of quinine in doses of from 20 to 30 centigrams which gave the best results. He does not consider it as a specific, but as a powerful neurosthenic which fulfils one of the principal indications of treatment. In certain cases he employed arsenic and opium with good results. Antipyrin is of too recent introduction in the therapeutics of diabetes to give a decided opinion as to its merits. As for bromide of potassium, which has also been much vaunted, it gave unfavorable results. Dr. Worms founded his observations on 41 patients whom he had been able to follow for some time and some of them are already cured.

At the same meeting of the Academy, Professor Ollier, of Lyons, read a note on *The Advantages of the Resection of the Hip-joint in Cases of Suppurative Coxalgia*. He stated that since 1860 he practiced this operation about fifty times. It was the sub-periosteal method that he had employed. After the operation he endeavored to obtain ankylosis

of the joint. He considers that when the femur is ankylosed in a favorable position, with a slight flexion, the operated subjects may go through the hardest work and become indefatigable walkers. Once the ankylosis is established, there is no more fear of secondary displacements, nor the return of tuberculous or inflammatory foci. M. Ollier concluded his note by recommending that in the great majority of the cases of suppurative coxalgia ankylosis should be obtained. However, articular mobility may be preserved when early resection is practiced, that is to say as soon as an abscess around the articulation is suspected or established, because then the extent of the lesions of the soft parts being reduced to the minimum, a very complete reparation may be expected. Nevertheless, M. Ollier does not always approve of this manner of proceeding, as in many cases of suppurative coxalgia in childhood cures may be obtained by more simple operations than resection, such as antiseptic opening of foci, iodoform injections, drainage, etc.

In a very interesting note on *The Treatment of Intestinal Occlusion by Electricity*, Dr. Larat begins by observing how often the diagnosis of the cause of intestinal occlusion is difficult. Nearly always, one is in the presence of a tympanitic intestine, preventing all palpation. He points out also the complete uselessness of purgatives when the intestine is impermeable. In such cases, repeated purgations serve only to excite vomiting. When relief of the bowel is obtained by electrization it presents different forms; sometimes it is sudden, gaseous and stercoral, sometimes it takes place slowly, occupying several days. One sitting alone of electrization is often powerless to obtain it. On an average, four or five sittings are necessary to obtain the desired result. Of nineteen cases reported to the Academy of Medicine, the author cited six successes. In conclusion, he believes himself justified in deducing from these facts that intestinal galvanic electrization deserves to be employed in all cases of occlusion, as soon as the medical means have failed, and when the obstacle is evidently insurmountable by purgatives, on which one should not insist too much.

Dr. Gaucher, of Algiers, recommends the following abortive treatment for whitlow. He says it is sufficient to moisten slightly the painful part and a little around it with some water, and to pass over this surface a stick of nitrate of silver. A few hours after the skin becomes black, all pain disappears, and the inflammation is arrested. The blackened epidermis receives no dressing and in six days the black color disappears. The author was induced to try this remedy in a case of a fit of gout. The patient had his great toe swollen at its base, it was painful to the touch, a little red, and the seat of lancinating pains which hindered the rest of the patient. The painful articulation was moistened and rubbed over with a stick of

the nitrate of silver. The next day the joint had diminished in size and was covered over with a black skin. The pain completely disappeared a quarter of an hour after the painting, and the patient got up to follow his occupations.

The hydrochlorate of cocaine is so much in vogue that a writer in the *Formulaire Mensuel* thought it necessary to remind his readers that when this drug is prescribed associated with energetic bases or their salts, cocaine is precipitated. Thus, in a gargle containing borax or a mixture containing lime water, precipitates are produced not only with cocaine, but also with a large number of vegetable salts. The practitioner will therefore direct to be written on the label, "shake each time." Without this precaution the first doses of the medicament may be inefficacious, and the last, on the contrary, much more active. A. B.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

American Academy of Medicine—Dr. W. Gilman Thompson's Paper on the Therapeutic Value of Oxygen.

At the last meeting of the Academy of Medicine Dr. W. Gilman Thompson read a paper on *The Therapeutic Value of Oxygen*, and in connection with it gave a demonstration of the effects of high pressures of oxygen upon animals. The first question he took up was whether an increased pressure really caused more oxygen to be absorbed by the system. Under any circumstances, he said, the hæmoglobin of the blood could take up but a very limited amount of oxygen, and the same was true of the blood-plasma. He pointed out the incorrectness of the old idea that animals could not live in pure oxygen, the system being burned up, as it were, by the increased tissue changes excited by it, and referred to the experiments of Dr. Andrew H. Smith in 1869 and 1870 in proof of this. His conclusion was that very little additional oxygen could be made to enter the system by any amount of pressure that would not be injurious.

He then exhibited the apparatus which he had constructed for the purpose of exposing animals to high pressures of oxygen. It consisted of a strong iron cylindrical chamber, with glass-covered openings at each end, in which the animal to be experimented upon was placed, and to this chamber oxygen was supplied at any degree of pressure desired from a cylinder containing the gas at a pressure of 225 lbs. to the square inch. Two animals, a monkey and a pigeon, which had been subjected for one hour to a pressure of 30 lbs. to the square inch of oxygen, in addition to

the ordinary pressure of the atmosphere, 15 lbs., were taken from the chamber in an apparently perfectly normal condition.

Dr. Thompson next proceeded to report with more or less detail a series of experiments he had made upon healthy animals; these being dogs, cats, pigs, monkeys, guinea-pigs, pigeons and alligators. It was found that all the animals could exist comfortably in the oxygen until a pressure exceeding thin atmospheres was reached. The higher the order of the animal experimented upon the more quickly it became affected. As a rule, a decided fall of temperature, often amounting to from 4° to 6° F., was observed; and only in cold-blooded animals was there any rise of temperature. Similar results had been reported by Valenzuela in a paper read before the Royal Academy of Madrid. This marked decrease he did not believe was to be attributed at all to the effect of the oxygen, but to the profound disturbances caused in the system by the high pressure employed. If, as was claimed by the older writers, a greatly increased tissue metamorphosis was caused by oxygen, this would unquestionably be accompanied by an increase, and not a diminution, of the body temperature. In such of the animals as died or were killed after being subjected to high pressure of oxygen he found pulmonary engorgement and dilatation of the right heart. The convulsions which usually resulted when the pressure was carried to a high point were, as a rule, quickly controlled by blowing off 5 lbs. of pressure. The cause of these convulsions, he said, was as yet undecided, but he was inclined to attribute it to the effect of the unequal diffusion of gases under different degrees of pressure. He also tried the experiment of subjecting animals on alternate days to high pressure of oxygen and to compressed air.

A second series of experiments was made upon animals in which abnormal respiration had been induced. Dyspnoea, he said, might be classified as being due to

1. Abnormal conditions of the air.
2. Abnormal conditions of the blood.
3. Obstructed circulation.
4. Diminished surface for aeration.
5. Neurotic influences.

In a cat in which dyspnoea was produced by cutting both vagi instant relief was afforded by exposing the animal to oxygen; while, on the other hand, the dyspnoea was increased by compressed air. In the second experiment a canula was introduced into the pleura of a dog. In the third pulmonary congestion was caused in a cat by injecting a solution of nitrate of silver into the lung tissue, and the dyspnoea resulting therefrom was greatly relieved by oxygen. In other experiments the lung was compressed by injecting considerable quantities of water into the pleura, and in still others the animals were bled to

the extent of many ounces. The results of these experiments, he said, went to show that oxygen does aid in a moderate degree certain types of dyspnoea.

In considering the therapeutic value of this agent Dr. Thompson stated that it had been employed, first, as curative in certain general diseases, more particularly of the blood and circulation; and, second, as a palliative in dyspnoea due to various causes. Of late its use had increased to such an extent that two or three hundred thousand gallons of the gas were now annually consumed in New York City alone. Among the other troubles, beside dyspnoea, in which it was claimed that it had proved of benefit, were anæmia, chlorosis, croup, chronic gastric catarrh, migraine, cholera, and opium poisoning. In anæmia, chlorosis, etc., he said he could see but little advantage over good fresh air in giving inhalations of diluted oxygen two or three times a day, as was the usual practice in such affections. It did not seem rational to him to expect that sufficient oxygen could enter the system under these circumstances to produce anything but a temporary effect at the best. In cases of blood poisoning, again, he had failed to see any benefit derived from oxygen. In certain subjective cases of dyspnoea it no doubt gave relief, but in a case of poisoning by illuminating gas which he had seen at the Presbyterian Hospital its administration was kept up for nearly three days without producing any effect either on the rate of respiration or on the cyanosis present. In cardiac diseases his experience with it had not been encouraging, and he referred particularly to a case of malignant endocarditis in which it proved of no avail in relieving the dyspnoea. In certain cases of asthma and of uræmic dyspnoea, however, it gave decided relief, and in such he believed it was an invaluable therapeutic agent; though not, of course, curative.

In the discussion on the paper Dr. J. West Roosevelt spoke of the relation of the amount of oxygen inhaled to that absorbed, and said that while the amount which entered the plasma or the hæmoglobin of the blood was comparatively small, he believed it was sufficient to cause appreciable results in many instances. As to the therapeutic value of oxygen, in the neurotic form of dyspnoea we had a condition in which the mere act of inhalation and the engaging of the attention of the patient would often have a beneficial effect. In anæmia he had met with fairly good results with oxygen, though the patients improved less rapidly than under the use of iron. If in any case the hæmoglobin was not saturated an improvement showed that more oxygen was carried than under ordinary circumstances. On the whole, oxygen had proved of considerable value in his experience, and in cases of diminished surface for aeration he had seen cyanosis decidedly improved under its use.

Dr. George L. Peabody was the most skeptical of any of the speakers in regard to the efficacy of oxygen. So many circumstances were involved, he said, in estimating the value of an agent like this, that it was difficult to arrive at positive conclusions respecting it. Thus, when it was not the only therapeutic agent employed it was impossible to say just how much benefit was derived from it; and this difficulty was further increased in diseases which naturally tend to recovery. From all that he could make out from reading and clinical observation there seemed to him good reason to doubt the alleged efficiency of oxygen, and personally he believed that, as a rule, quite as much relief could be obtained from ordinary fresh air. It might be tried, however, in maladies attended with dyspnoea in which the blood is unchanged, such as pneumonia, emphysema, croup, and asphyxia from noxious gases; although, as Dr. Thompson had stated, in poisoning by illuminating gas it had failed to give relief. There was no justification, he thought, for the extensive use of oxygen in such diseases as anæmia, chlorosis, lithæmia, etc. Its absorption depended, probably, on the amount of hæmoglobin in the blood at the time the oxygen was administered; but in any event the amount absorbed was unquestionably very small. Although the pulmonary gymnastics of the inhalations might have a beneficial effect in certain instances, there were other remedies which could be employed with much greater advantage. That the use of oxygen hastened recovery in such cases he could not believe, and the recognized facts of physiology were certainly at variance with any such conclusion.

Dr. Beverley Robinson, on the other hand, was a most enthusiastic believer in the practical utility of the remedy. He said that he differed entirely from Dr. Peabody, and that his clinical experience afforded the most conclusive proof of the immediate and marked relief resulting in many conditions from the use of pure oxygen. The purity of the gas he considered a point of very great importance, and he said that one make of gas which he had formerly employed gave such poor results that he abandoned its use. There was a gas now manufactured in New York which was said to contain a certain proportion of nitrogen monoxide, from which he had obtained very satisfactory results, and it was worthy of note that Brown-Séquard had expressed his opinion that nitrogen was of great service in preventing the irritating and intensely exciting effects of oxygen alone.

In anæmia he had found that those cases were most improved in which oxygen was used in connection with iron. In albuminuria connected with atrophic nephritis he had found the general nutrition of the patient improved under the use of oxygen; the digestive and assimilative powers

being greatly assisted by it. Even in plithisis, while it did not have a curative effect, it might prove beneficial. In the first place, the inhalations caused the patient to thoroughly expand his lungs; secondly, oxygen was itself an antiseptic; and thirdly, it had the effect of improving the general nutrition. As had been well said, oxygen was really prescribed every time that a patient was sent to the mountains, to Southern California, to the plains, or on a sea voyage. That there were many cases in which it was impossible to send patients away, and he believed it was possible to stimulate the hæmoglobin in the blood, and thus to enable the patient who remained at home to carry more oxygen. In the use of oxygen he did not think we should be guided so much by experimental researches as by practical clinical experiences. Leaving out of consideration those cases in which he believed it had a decidedly curative effect, there were certainly many others in which the last hours of patients could be rendered much more comfortable by resorting to the use of oxygen.

Dr. Walter Mendelson took much the same view of the subject as Dr. Peabody. While it was true that in anemia he had some quite marked results under the use of oxygen, he did not believe that the benefit noticed was in reality due to this agent. In this connection he cited the case of an old man who inhaled ten gallons of oxygen a day, and became greatly improved. This improvement, however, he was convinced was due to the systematic expansion of the lungs and to the moral effect of the knowledge that something out of the common was being done for him. In cases of dyspnoea from various causes he had seen more or less relief afforded by oxygen, yet all the patients died. Still, as Dr. Robinson had remarked, it was possible that their last moments were rendered more comfortable by the inhalations.

Dr. M. P. Jacobi said that the amount of oxygen which the hæmoglobin carries varies under different circumstances. In asphyxia of various kinds the physiological capacity of the blood remained the same, and therefore the indication was to administer oxygen. The correctness of this had also been shown by clinical experience. In anemia, and especially chloro-anæmia, on the other hand, the hæmoglobin was diminished. The condition was precisely the reverse from that met with in asphyxia, and we could not cause a much greater amount of oxygen to be absorbed.

Dr. Andrew H. Smith said he was gratified to find that the work which he did twenty years ago for the most part still remained good. At that time he had demonstrated that animals could live perfectly well for four days in pure oxygen; care being taken to remove the effete products of respiration. It was his opinion that under ordinary circumstances the blood is not fully saturated with oxygen, and that the point of saturation

corresponds with the physical demand. This allowed a pretty wide margin, and it was perhaps within this margin that a considerable amount of oxygen could be absorbed by the blood. Thus the demand for oxygen was much greater in athletes engaged in violent exercise than in individuals making but little physical exertion. Therapeutically, he had seen the greatest benefit derived from oxygen in catarrhal conditions of the air-passages, such as was met with in suffocative bronchitis. In such cases he was at a loss how to explain the relief afforded by the oxygen, unless it was a fact that under these conditions the blood did not take up as much oxygen as the system required. Dr. Smith also said he had used oxygen with satisfactory results in opium poisoning.

In closing the discussion Dr. Thompson said that convulsions were produced in the animals experimented on by the rapid increase of the pressure, and that such convulsions were quickly relieved by the rapid withdrawal of a portion of the pressure. He could not agree with Dr. Smith in his opinion regarding the saturation of the blood with oxygen, since he thought there could be no question that even under ordinary conditions the hæmoglobin was practically saturated with oxygen. He also believed that Dr. Robinson was unquestionably mistaken in attributing any irritating effects to oxygen. This was entirely disproved by his own and by Dr. Smith's experiments with animals; and it had been repeatedly demonstrated by others that pure oxygen has no irritating effects whatever. It produced no burning up of the tissues, as had been formerly supposed, and he could see no advantage over ordinary air in the nitrogen monoxide referred to.

During the evening a cat and a dog were successively subjected to progressively increasing pressures of oxygen in the pneumatic chamber. When the pressure reached 80 pounds to the square inch the cat was seized with a convulsion, and the dog had a convulsion when the pressure reached a little above 45 pounds. Both animals recovered after they were restored to the air.

P. B. P.

MISCELLANY.

THE 75,000 EDITION.—*The American Lancet* says: "On May 25th, THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION issued an edition of 75,000 copies, thus reaching nearly all the physicians of the United States. It is hoped in this manner to interest more physicians in THE JOURNAL, and the American Medical Association. Especially is it hoped that it may attract a large number to the coming annual meeting at Newport. A pretty full preliminary notice of this meeting is given so that a fair idea may be had respecting it. Incidentally, it may be said that the edition fully pays for itself, without any reference to the regular subscribers, or the members of the Associ-

ation, so that any advantage that may accrue to either will be a clear gain."

The New York Medical Journal says: "THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.—An edition of 75,000 was recently printed, enough to enable our excellent contemporary to bring itself to the notice of almost every physician in the country."

The Weekly Medical Review says: "With commendable zeal the editors of THE JOURNAL have issued 75,000 extra copies to the medical profession. This copy contains a lengthy list of the titles of papers to be read at the coming meeting of the Association. THE JOURNAL also contains a concise description of 'Newport-by-the-Sea,' and the neighboring places of interest, illustrated by near a dozen elegant plates. These extra copies which have been mailed to the physicians throughout the country are well calculated to arouse a more universal interest in the coming meeting, which will be held June 25th to 28th. The prospects are that the meeting will be larger than any ever yet held by the Association. The extra number of THE JOURNAL also contains a number of valuable contributions to medical literature and a brief review of the history of the Association."

Dr. R. J. Dunglison, of Philadelphia, writes us: "I think the Extra Edition a great success."

Dr. A. L. Hummel, of Philadelphia, writes us: "Your Special is a beauty. Please send me two more copies."

The Medical Times and Register says: "THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION comes out on May 25, with an edition of 75,000 copies. THE JOURNAL gives evidence of careful and competent editorial supervision; and if it is now under a temporary management, the Association can scarcely do better than make the present arrangements permanent."

The College and Clinical Record says: "An extra edition of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 75,000 copies, was issued on May 25th. It is a very attractive number, and the enterprise and judgment displayed in both the publication and editorial departments reflects much credit upon those who carried the project to a successful execution. Certainly the great bulk of the medical profession will now be thoroughly informed as to the objects of the American Medical Association, the publication and merits of THE JOURNAL, and the practicability and desirability of medical men becoming members of the Association, which they can now do with facility, either by attendance as delegates or by direct application at any time, merely forwarding a certificate of good standing in their State or local Society, and five dollars, annual dues, to the Treasurer of the Association, Dr. R. J. Dunglison, Philadelphia. They receive THE JOURNAL, for the year free."

The American Practitioner and News says: "THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION recently added 75,000 extra to its regular edition. We sincerely hope that the enterprise of its management may be rewarded by the return of 75,000 *bona fide* subscribers."

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from June 1, 1889, to June 7, 1889.

Capt. Geo. F. Wilson, Asst. Surgeon U. S. Army, resignation was accepted by the President, and took effect May 31, 1889.

By direction of the acting Secretary of War, Capt. James C. Merrill, Asst. Surgeon, is detailed as a member of the board of medical officers appointed by par. 9, S. O. 108, May 10, 1889, from this office, to meet at the U. S. Military Academy, West Point, N. Y., on June 1, 1889, or as soon thereafter as necessary, to examine candidates for admission to the Academy, etc., vice Capt. Fred. C. Ainsworth, Asst. Surgeon, hereby relieved as a member of the board. Par. 4, S. O. 127, A. G. O., June 3, 1889.

Capt. W. O. Owen, Jr., Asst. Surgeon, leave of absence for seven days granted in Order 18, c. s., Ft. Gibson, I. T., is extended twenty-three days. Par. 2, S. O. 67, Hdqrs. Dept. of the Missouri, Ft. Leavenworth, Kan., May 29, 1889.

First Lieut. Jefferson R. Keen, Asst. Surgeon, leave of absence granted in S. O. 48, Dept. of the Platte, May 15, 1889, is extended fifteen days. Par. 3, S. O. 129, A. G. O., June 5, 1889.

APPOINTMENTS.

Philip G. Wales, appointed Asst. Surgeon, with rank of First Lieut., from June 7, 1889.

Theodore F. De Witt, appointed Asst. Surgeon, with rank of First Lieut., from June 7, 1889.

Benjamin L. Ten Eyck, appointed Asst. Surgeon, with rank of First Lieut., from June 7, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending June 8, 1889.

Asst. Surgeon J. J. Page (retired), granted one year's leave of absence to leave the United States.

Thos. B. Bailey, appointed an Asst. Surgeon in the Navy May 23, 1889.

George H. Barber, appointed an Asst. Surgeon in the Navy May 23, 1889.

George Rothganger, appointed an Asst. Surgeon in the Navy May 24, 1889.

George Tucker Smith, appointed an Asst. Surgeon in the Navy June 3, 1889.

Asst. Surgeon T. B. Bailey, ordered to the receiving ship "Dale," at Washington, D. C.

Asst. Surgeon Geo. H. Barber, ordered to the receiving ship "Vermont," at New York.

Asst. Surgeon F. N. Ogden, ordered to examination preliminary to promotion.

Asst. Surgeon P. H. Bryant, detached from Naval Hospital, Chelsea, and granted a month's leave of absence.

Medical Director H. O. Mayo (retired), granted one year's leave of absence, with permission to leave the United States.

PATHOLOGICAL SPECIMENS, WITH ACCOMPANYING HISTORIES.

*Presented before the Medical Society of the District of Columbia,
May 21, 1889.*

BY JOSEPH TABER JOHNSON, M.D.,
OF WASHINGTON, D. C.

[Reported for THE JOURNAL.]

Case 1.—Ovaries and tubes from a white lady, æt. 34; no children, though she had been married fourteen years. History of pelvic pain and chronic invalidism for nearly twenty years. Had undergone much treatment by many physicians in different cities without benefit, and was now nearly worn out. Upon examination, found enlarged ovary on one side and an adherent mass on the other, such as usually passes for pelvic cellulitis. Dr. J. recommended immediate removal of diseased organs. Patient was delighted at a definite proposition to do something, and she entered his private hospital for that purpose. Appendages upon both sides removed; ovary upon right side was as large as his fist, and contained blood and pus. Appendages upon left were densely matted together and adherent to anything they touched. Recovery has been perfect. It is now a year since the operation, and Mrs. S. is in perfect health.

Case 2.—Mrs. D., æt. 32; white, wife of a clergyman; mother of seven children; had been an invalid for ten years; confined to her room for last three years, and to her bed for past year; sent to him by Dr. Stuart Harrison, of Anncostia. One ovary very much enlarged; condition very similar to Case No. 1. Same operation and same result; done in his private hospital. Returned six months later with pains in the rectum and pelvis; pelvic pains relieved by galvanic current. Dr. P. S. Wales, late Surgeon-General U. S. Navy, saw her with him, and discovered a fissure of the anus, which he completely cured by thoroughly dilating the sphincter under ether.

Case 3.—Enlarged tubes with ovaries, from a case of pyo-salpinx, in a single colored girl, æt. 28 years. Had been a great sufferer for some years; referred to Dr. J. by Dr. Mary Parsons. Operated in private room in Providence Hospital.

Rapid recovery, and continues well; gained thirty-five pounds in last six months.

Case 4.—Ovaries and tubes from Mrs. W., a widow, aged 36, who was suffering from a bleeding uterine myoma; had treated her three months with ergot and electricity without effect, except to tone up her system somewhat; was employed by the Government, but lost her place on account of continued absence; was unable to work, and had to be supported by friends. Operated last January. Patient is now well; has lost no blood since the removal of appendages in Providence Hospital.

Case 5.—Ovarian cyst nineteen pounds from Miss R., aged 23. White; single; sent by Dr. Chapman, of Glymont. Operated in his private hospital February 14, 1889, when her temperature was 103°, pulse 130°, and respiration 40°. Complete and immediate relief; no bad symptoms during recovery, except from slight stitch hole abscesses; is now at home, and perfectly well.

Case 6.—Blood-clots, ovary and tube from Mrs. B., who was operated on for symptoms resembling extra-uterine pregnancy. Saw her first with Dr. Fry; patient suffered with constant pain and bloody discharge; had a mass in left iliac fossa, resembling a fibroid; pain and tenderness increasing, and evidence of pus developing. Dr. Fry had her removed to Dr. Johnson's Private Hospital, where she was operated on four months ago. A large abscess of left ovary was opened; a pint of very offensive pus was evacuated; cavity washed out and drained; drainage tube remained in two weeks, and gave exit to much offensive fluid. More than a handful of large, blackish blood-clots came out of the abdomen, and from their size and age were supposed by Dr. Johnson to be portions of placenta; but Dr. Gray, of the U. S. Medical Museum, reports them to be old coagula. Patient had been in bed eleven weeks when operated on. She now reports herself as perfectly well. The other ovary was not disturbed.

Case 7.—Two enlarged ovaries and tubes from Miss G.; white; æt. 23; single; has been a sufferer for ten years; was sent to him by Dr. Bayne, who had treated her for several years for menstrual epilepsy and painful periods. Had been under Dr. Johnson's care four years. He had fre-

quently urged her to have her appendages removed. They were known to be enlarged—in a state of chronic inflammation and adherent. After one of her attacks of convulsions, her bladder lost its power to contract, and for three years and five months her water was passed only through a catheter, which she finally used for herself. Under the frequent and prolonged use of the faradic current, she regained the power to empty her own bladder. Last fall she had a pelvic peritonitis, which kept her in bed over a month. The left ovary began to enlarge very rapidly, and kept her house-bound. She entered Dr. Johnson's Private Hospital in January, and was operated on. One ovary was as large as a child's head, and contained over a pint of offensive pus. The other was as large as a lemon. The patient made a slow recovery, and left the hospital in six weeks. Being septicæmic when operated on, she has done fairly well. She is now going about, and has gained at least twenty-five pounds, and expresses herself as being a new creature.

Case 8.—Large ovarian cyst, from a white married lady, æt. 61 years. Tumor had been growing less than a year. Patient had been confined to her room for a month with typhoid symptoms. Pulse about 100°, but temperature ranging from 100° to 103° every evening; tongue very brown and dry. Was removed from a boarding-house to Dr. Johnson's Private Hospital, and operated three days later. Third day after removal of tumor, symptoms all disappeared. She made an uneventful recovery, and left the hospital in five weeks. She is now perfectly well. Tumor weighed 26 pounds; was sent to Dr. J. by Dr. Gardner.

Case 9.—Supra-vaginal hysterectomy. Uterus, tubes and ovaries removed, with a fibroid tumor weighing four pounds. Saw the patient with Dr. Brownell about three weeks ago, when she was suffering acutely with symptoms of intestinal obstruction. Dr. B. had attended her for a week, and had been unable to cause a movement of her bowels. Had been compelled to administer many hypodermic injections of morphia to quiet her agony. Her abdomen was enormously distended with gas; her temperature was about normal, but her pulse had been 120° for three days. Dr. Johnson had seen the patient over a year before in consultation with several physicians, in reference to the removal of a fibroid tumor of the uterus. The patient was anxious for an operation, but three out of five doctors were opposed to its removal, and a course of electrical treatment was recommended. This was continued for about four months without any marked benefit under the skilful management of Dr. McArdle. Patient had suffered in the meantime from attacks of indigestion. Upon a vaginal examination the fibroid was now found to be entirely filling the pelvis, and

Drs. Johnson and Brownell thought the tumor was the cause of the intestinal obstruction, and that its immediate removal offered the only hope of her relief. Though there was great distention of the abdomen, constant vomiting, and a pulse of 120, yet with a temperature at about 99, it was thought that there was little or no peritonitis. The patient and her family were ready and anxious for an operation. It was decided on at noon, and done at 4 P.M. The only difficulties experienced in the operation were in keeping the distended intestines from escaping, and in getting the tumor out of the pelvis. It was finally drawn up with Tait's corkscrew pulling it, while two fingers in the vagina pushed it above the brim of the pelvis. There were no adhesions except to the sigmoid flexure, which was completely flattened out. Keath's clamp was applied at about the internal os, and the tumor cut away; pedicle treated externally, and the wound closed in the usual way. It was thought that the removal of the tumor would remove the obstruction, and no extensive search was made for any other trouble. Patient was very much more comfortable after the operation, and frequently expressed herself as being free from pain. Operation was done on Sunday. The difficulty was not relieved, and she died on Thursday of intestinal obstruction. The autopsy showed everything very satisfactory about the operation, but revealed a tight constriction of the colon at the point where the transverse merges into the descending colon, in which was a perforation large enough to admit the big end of a lead-pencil. Considerable intestinal contents had escaped. About six inches of the gut was removed, and with the tumor was presented to the Army Medical Museum. Upon examination, Dr. Billings reports the obstruction to be "cancer of the intestine." We have the sad consolation, therefore, of knowing that her life could not have been saved by any operation short of a resection of the intestine, and the malignant deposit was not discovered until the autopsy.

Case 10.—*Supra vaginal hysterectomy.* Soft, rapidly-growing myoma of the uterus, weighing 20 pounds, removed from Miss E.; white; æt. 31. First noticed an enlargement four years ago; had only been troublesome for about a year; was anxious to have it out. Operated in Providence Hospital. Many and very vascular adhesions about upper part of tumor, and to the omentum. Some of the vessels were as large as index finger. Koeberly's *serre neud* applied to pedicle, and treated as recommended by Bantock. Later: patient has made a good recovery; has a normal pulse and temperature; is now in her twenty-fourth day.

Case 11.—Tubes and ovaries from Miss B., æt. 24; white; a seamstress, who was prostrated on account of loss of blood from a bleeding uterine myoma the size of a large cocoanut. Had been in the Homeopathic Hospital off and on for about

three months; was entirely supported by kind friends. Operation had been a complete success. She has written him this week that she feels better and stronger and happier than at any time for a year past.

Case 12.—Cancer of the ovary, large as a child's head. Was operated on in Dr. Johnson's private hospital. Fluid collection in abdominal cavity, mistaken for a cyst. Upon disturbing the mass, it began to bleed, and the only way to arrest hæmorrhage was to ligate and remove it. Cavity irrigated with hot water, and drainage tube put in. Recovered from the operation, and went home in five weeks, probably to die soon from an extension of the cancerous disease.

Case 13.—Large ovary and part of tube removed from Mrs. S. two months ago; had been confined to bed two months previous to operation on account of agonizing attacks of pain. She gave the history of a miscarriage in the sixth week, and much of her sufferings and frequent bloody discharges from the uterus were attributed to her own bad management. It was supposed that the fœtus had escaped, and that portions of sedundines still remained. Upon examination, the uterus seemed to be enlarged, retroverted, and exquisitely tender. So much pain was given by pressure that several of the physicians who had attended her were unable to make a satisfactory examination. I saw her with Dr. J. R. Bromwell about ten weeks ago, and after learning the history and examining the patient as well as we could, were divided in opinion as to whether we had an enlarged uterus or an extra-uterine pregnancy to deal with. Her terrible attacks of pain and the bloody discharges from the uterus caused us to think the latter condition might be present. It was decided finally to etherize her—dilate the uterus and remove anything abnormal which we might find in the cavity. This was done a week later, and the uterus was found to be only slightly enlarged and entirely empty. Upon the left side, however, we found a mass the size of one's fist, which had been mistaken for the enlarged and retroverted fundus uteri. Its very great tenderness had prevented manipulation, and it was not until she was etherized that we could determine that the mass was not the uterus. Just exactly what it was no one could yet say, but it was believed to be an enlarged ovary with an enlarged tube on its upper surface. It might be extra-uterine pregnancy. While our diagnosis was not certain, our opinion was that this enlargement was the cause of all her trouble, and that it ought to come out. A week later the abdomen was opened and Dr. J. removed the left ovary, which was larger than a lemon. It was very black and very soft. In enucleating the ovary from its bed of attachments, half a pint of black blood-clots welled up into his hand, and were guided out of the cavity. The abdomen was thoroughly irrigated, a

drainage-tube put in, and the incision closed. The patient has made a good recovery. Am inclined now to think it was extra-uterine pregnancy, though Dr. Lamb says it is only blood-clots. Several of Mrs. S.'s family had died of cancer, and the fear of malignancy made the patient and her family more ready for an early operation. Mrs. S. vomited constantly for six days after the operation, and was only nourished through the rectum. This caused no pain and no rise in pulse or temperature. She has a good appetite and digestion. She has gone to Atlantic City for the summer.

ON THE DIAGNOSIS OF PREGNANCY IN THE EARLY MONTHS.

*Read before the Medical Society of the District of Columbia,
January 30, 1889.*

BY LLEWELLYN ELIOT, M.D.,
OF WASHINGTON, D. C.

In speaking of the diagnosis of pregnancy in the earlier months, I desire to state that I refer to the time previous to the appearance of the positive signs, or, in other words, previous to the fourth month. The subject is one of very great importance, both to the patient and to the medical man, for upon his decision will rest, in many cases, the domestic happiness of families, especially when considered with reference to the younger female members. An error in diagnosis can never be remedied, for it matters not whether we pronounce for or against pregnancy and the final outcome of the case be different from our prediction, the error will live long after the case has been forgotten by the physician. It is this possibility of injuring our reputation that makes the subject of so much greater importance and demands that medical men should be conversant with all the signs of pregnancy, presumptive, probable, and positive. When a married woman desires to know whether or not she is pregnant, she will freely confide her symptoms to her physician, knowing that this is the only way for him to form a positive opinion, even allowing the vaginal examination, but how different is it, as we all know, when a young woman has fallen from virtue, becomes pregnant and seeks treatment for a suppression of the menses and a nausea and sick stomach in the morning. In such a case there is frequently the greatest difficulty in forming a diagnosis, for she will deny all symptoms, she will admit nothing, and assume the rôle of injured innocence when closely interrogated as to her habits, protesting all the while that the suppression is but the result of exposure to the cold and wet; that she never was regular; that her appetite and digestion never were good; that she has backache, which is always a premonitory symptom with her of the approach of the menstrual period. Now what excuse could we

have for proposing an examination of the breasts, an inspection of the vagina for its discoloration, an examination of the cervix, an application of the thermometer, or an examination for Hegar's shortening of the neck, in a case of this kind? Our suspicions might make us anxious to apply any or all of these tests, but the patient would refuse to see the necessity of it and seek advice from some one who would not ask "impertinent questions." In a case like this the pulse rate is, in my opinion, the most reliable sign, for its application requires neither exposure nor vaginal examination, it is simple, and is a sign not generally known to women, and will guide us in our further disposition of the case.

Let us see what are the signs of pregnancy in the earlier months, previous to the positive signs of this condition, that is to say, previous to the end of the fourth month.

The first sign of pregnancy is the suppression of the catamenia, then follows a bilious attack, a disordered state of the stomach, with nausea and vomiting, vesical tenesmus and irritability, kyesteine in the urine, salivation, changes in the mammae, flattening of the abdomen, softening of the cervix uteri, depraved appetite with longings, violet discoloration of the mucous membrane of the vagina, and descent of the uterus.

We must remember that the probable and presumptive signs of pregnancy may or may not be the result of gestation; that they may be the effects of various morbid conditions of the uterus or other organs of the system, with which pregnancy has no connection, and that the positive signs are evidences of undoubted value.

In regard to the suppression of the menstrual discharge, suppression may result from other causes; newly-married women sometimes skip two or three months and then become regular, again it may not be suppressed at any time during the gestation. I have seen it occur three successive months after impregnation. The vomiting and nausea may follow from other causes. Depraved appetite and longings for various articles of diet are reliable signs. I have known cases in which enormous quantities of starch have been consumed by the patient. The breasts begin to change about the second month, the nipple becomes more sensitive, projects, swells, and assumes a darker color; the areola is completed about the fourth month.

Neuralgias, hysteria, syncope, a sensation of increased bodily heat, dizziness, change of disposition, headache, occasional rigors, pigmentation and swelling of the face, together with various nervous derangements, very frequently occur.

Kyesteine has been found as early as the fifteenth day, and frequently at the second month, but its presence is most characteristic from the third to the sixth months, and diminishes from the seventh month.

Chloro-anemia may result from the disordered

gastric function and the altered condition of the blood, to improve after the fourth month. At from three to three and a half months, the abdomen begins to regularly and permanently enlarge. The vaginal mucous membrane becomes discolored, assuming a blue or violet color, as this may be found in all cases in which there is a predisposition to a vascular condition of the genito-urinary apparatus it loses its importance as a diagnostic sign. The uterus retains its normal position during the first three months, but the fundus rises as the organ enlarges, while the neck and inferior part subside more towards the floor of the pelvis. This I take to be the principle of Hegar's shortening of the neck of the uterus. At the fourth month the uterus may be felt three or four fingers' breadth above the pubis. The lips of the os uteri begin to soften towards the end of the first month; at the fifth month the cervix diminishes, to be gradually obliterated at the end of term.

M. Larcher, in 1828, and again in 1857, called attention to the hypertrophy of the heart, and M. Blot has confirmed his observations. This hypertrophy, like that of the uterus, passes away after

* Delivered May 1.

delivery. J. Braxton Hicks has published several articles in which he places great faith in the uterine contractions which occur throughout pregnancy, at a time varying from three to twenty minutes and continuing for a space of three to five minutes. I place reliance upon the pulse test, Jorissenne's sign, and have employed it for the past seven years, in a great number of cases.

There can be no possible objection raised to counting the pulse, and the result has removed all doubts in those cases in which I have employed it.

The diagnosis by Hegar's sign, by the thermometer, or by the softened condition of the os uteri, I have not been able to practice sufficiently to draw any satisfactory conclusions, as in each of the cases I have been controlled by the pulse test.

The principal object of this paper is to call attention to the value of the pulse test in those cases where much professional tact is required to solve the question of pregnancy. The following may be cited as a few of the cases in which I have applied this method of diagnosis:

The value of the pulse test consists in the sameness, or very little variation in the number of the radial pulsations, and while it is not infallible it possesses enough certainty to give it a place in the positive signs in forming the diagnosis of pregnancy. According to Jorissen's article published in the "Ann. Soc. de med-chir de Liege," vol. xxi, he has employed this sign since 1878, and some of the particulars of his cases are most conclusive. He refers to an article of H. Schapiro, published in Russian, in 1881, but I have seen neither the article nor the review of it which was published March 4, 1882, in the *Centralblatt für Medicinischen Wissenschaften*.

AN INTRODUCTION TO THE STUDY OF PNEUMONIC FEVER.

BY EDWARD F. WELLS, M.D.

SEVENTH PAPER—PREVALENCE.

AGE.

From the cradle to the grave—from the earliest infancy to the greatest age—man is liable to attacks of pneumonic fever. The newly-born babe, the prattling child, the rollicking boy and winsome girl, the bashful youth and demure maiden, the man in his strength and his mate in her loveliness, the sedate of both sexes as they descend the decline of life, and the aged totterers upon the brink of the grave; all furnish victims to this devouring enemy of mankind.

Although no age is exempt, yet the disease is met with much more frequently at some periods of life than at others. During early childhood pneumonic fever finds easy and exceedingly numerous victims. From 5 to 20 years of age the mortality sinks to its lowest level. From 20 to 40 years the proportion is increased somewhat,¹ to be again considerably augmented during the next score of years.² Old age comes on with a large—the largest—and increasing prevalence.

Grisolle³ says that it is "a disease very frequent from infancy to 20 years of age, . . . comparatively frequent from 20 to 40, less so from 40 to 60," and very frequent, and also very fatal, after 60 years of age."

Whether or no this malady is common in infancy has been a strongly controverted point by different writers.

Swett,⁴ Weber,⁵ Fox⁶ and others⁷ say that the disease may even attack the foetus *in utero*, and Hayne⁸ has recorded the particulars of such a case.¹⁰ It is perfectly well established that infants in the very earliest hours or days of life may be so attacked.¹¹ A fine example of pneumonic fever in an infant 15 days old, subjected to autopsical examination, is recorded by Smith.¹²

In the spring of 1875 a male and a female child, twins, aged 3 weeks, were suddenly attacked with a short, hacking, and apparently painful cough, extreme shortness and rapidity of breathing, and elevation of temperature. They failed rapidly and died, one on the morning and the other during the afternoon of the third day. At the autopsy the pleurae of both were inflamed, coated with recent lymph, and their cavities contained a quantity of flaky and yellowish serosity. In both were patches of consolidation throughout both lungs. In one of the children the cerebral membranes were intensely congested, with minute points of extravasation in the pia mater.

Another fatal case came under my notice in 1879, in which the patient was only 1 week old. A post-mortem examination was not allowed.

Juergensen¹³ states that at least three-fifths of all the cases of pneumonic fever occur between the ages of 1 and 14 years. Laennec¹⁴ says that children are "very subject to the disease, and the

¹ Green, in Quain's Dic. Med., N. Y., 1883, p. 574, says that it is extremely frequent at this period, but this opinion is at variance with my statistical investigations.

² See Cullen, Prac. Phys., Phila., 1792, Vol. i, p. 182.

more so the younger they are." Audral¹⁵ affirms that "children are particularly prone to attacks of this malady, . . . it being one of the most powerful causes of the mortality of early life." Guersant¹⁶ was of the opinion that "three-fifths of the children that die in the hospitals of Paris between birth and the conclusion of the first dentition die of pneumonia." Gerhard¹⁷ says that few children die without pulmonary inflammation.

Lombard¹⁸ says: "From the first to the eighth day of life pneumonia constitutes seven-tenths of all the sickness, and one-sixth of the deaths are caused by this disease. As the function of the lungs is better established there is a falling off in the number of cases. In the second week pneumonia constitutes two-ninths of the sickness. Beyond the third week there is a considerable diminution in the proportion of cases. Between 6 weeks and 2 months it causes two-ninths of all sickness. From 2 to 6 months only one-tenth, but afterwards the ratio increases again. From 1 to 2 years it causes one-third of all sickness. From 2 to 6 years the proportion falls to from one-fourth to one-fifth. From 6 to 8 years it is a trifle greater. Between 8 and 11 years the proportion sinks to between one-fourth and one-sixth. In the twelfth year pneumonia is more frequent than in the immediately preceding or following years."

Of 608 cases analyzed by Louis,¹⁹ 206 were under 18 years of age, 118 from 18 months to 14 years, and 284 from 14 to 83 years.

That the disease, contrary to the opinions of some,²⁰ is a very common one in early life, is also proved by the following facts gleaned from registration reports:

Of 1,553 deaths from pneumonic fever in Manchester, Liverpool and Birmingham in 1839, 1,131, or 73 per cent., were under 5 years of age. Of 25,145 deaths from this cause in England in 1866, 17,460, or 69.4 per cent., were below the age of 5. Of 2,228 deaths from this disease in New York City in 1878, 1,134, or 54 per cent., were under 5 years of age. Of 60,675 deaths from this malady reported in twelve large American cities during recent years, 23,895, or 40 per cent., were below the age of 5. During a series of nineteen years in Massachusetts, twenty-four years in Vermont and fifteen years in Rhode Island, there were 46,563 deaths from pneumonic fever, and of these 17,284, or 37 per cent., were under 5 years of age. In the years 1883-4-5, in Ontario there were 3,797 deaths from this cause, 1,330, or 35 per cent., of which were under 5 years of age. In the United

States, in 1880, there were reported for analysis 63,079 cases of this disease, 19,004, or 33 per cent, of which were children under the age of 5 years.²¹

Reasoning from these statistics we are safe in estimating that at least one-third of all fatal cases of pneumonic fever are children under the age of 5 years.

It has been asserted that children are now more susceptible to pneumonic influences than formerly, but its more frequent appreciation in recent years is probably due to our improved diagnostics.

Thus, in the Vienna Institution for Children this disease was said to constitute but 2.3 per cent. of the total sickness at the beginning of this century,²² whilst fifty years later the proportion had risen to 7 per cent.²³

In this connection the difficulties of diagnosis in infantile pneumonic fever must not be underestimated. For an accomplished diagnostician these are by no means trifling, and we know only too well that, unfortunately, all persons who are by law empowered to write certificates of death are not of this class. There can be no doubt that a considerable number of children who are reported as having succumbed to "teething," "convulsions," "worms," "cerebral disease," etc.,²⁴ would be found to present the evidence of pneumonic inflammation were they subjected to necropsical examination. These remarks apply equally to many aged persons reported as dying from "coma," "cerebral disease," "apoplexy," "debility," etc.

These circumstances vitiate, to a certain extent, the value of all public mortality statistics. Hospital returns are but little more reliable, inasmuch as all ages do not alike frequent them.

Pneumonic fever attains its greatest prevalence in those who have passed the meridian of life.²⁵

Loomis²⁶ is of the opinion that fully 90 per cent. of the deaths of persons over 65 years of age are caused by this malady; in this, however, he is clearly in error, probably from trusting to individual impressions, rather than to statistics.

At the Soldiers' Home in Dayton 48 per cent. of all deaths in patients over 70 years of age are from pneumonic fever.²⁷

Humphrey²⁸ records a successful case of this disease in a female 104 years of age, and Lœber²⁹ one in a man of the great age of 110 years. In the United States in 1880, seventy-nine persons over 95 years of age died from this malady.³⁰

¹⁵ No attempt has been made to embody all the available material on this subject.

Total	1,067,585	6,066	6.05

SEX.

Pneumonic fever does not prevail equally in the two sexes—males being attacked oftener than females. This statement has been copied from

¹ Ziemssen's Handb. d. Spec. Path. u. Therap. Bd. v., S. 26.

² Statistik d. Pneumonic Wirzb. 1860.

³ Quoted by Lepine, Pneumonie. Wien, 1883, S. 16.

²⁶ Lungenentzündung. Leipzig, 1862, S. 74.

one text-book into another from time immemorial, and is always accompanied by the simple and plausible explanation that, inasmuch as the habits and occupations of males lead to exposure of all kinds to a greater extent than their congeners, they are, therefore, oftener the subjects of this disease. In other words, it is affirmed that males are not more predisposed to the malady than are females, but are merely more exposed to what has been supposed to be the exciting causes.

LaRoche⁵⁷ is quite clear on this point, saying that "there are facts sufficient on record to warrant the assertion that this greater prevalence of the disease in the first mentioned (male) sex is not due to an inherent susceptibility, but to the result, when it occurs, of a series of fortuitous causes; more particularly to the circumstance that males—owing to the nature of their avocations and mode of life—are usually more exposed than females to the causes of pulmonary inflammations; and that in places where exposure is equal in both sexes the disease manifests itself as frequently in one as the other."

Other writers have made similar statements. Thus, Swett⁶ says that males are attacked oftener than females because of increased exposure, for, "where the sexes are equally exposed to the vicissitudes of the weather the difference is not striking." Chomel³⁹ says that the apparent cause of this difference in the liability of the two sexes to attacks of the disease is in their work, and that in the case of young children and very aged persons this does not appear. Peacock⁶⁰ says that "the greater tendency to pneumonia in men is simply due to their exposure to the exciting causes of the disease." Fox¹ affirms that this difference between the sexes is not observable in the earlier periods of life, but it becomes apparent first at ages when the occupations of the sexes differ, and when the males are more exposed to climatic influences than females. When, however, the conditions of life for both sexes are identical, this relative disproportion in a great measure disappears.^{11, 12}

This is only partially, if at all, true for, independent of such influences, there is an inherent propensity in the male, greater than in the female, to take on this form of disease. Indeed the proportion of males over females attacked is greatest in the earliest years of life and at an age when both sexes are exposed in an equal degree to the vicissitudes of the weather and other alleged causes of the malady. In this instance, as in so

many others, we must accept the fact, although we remain ignorant of the cause.^{11, 12}

The facts above indicated are clearly set forth in the following tables and statements:

In England and Wales the death-rate from pneumonic fever is 1.34 and 1.06 per 1,000 for males and females respectively.⁶⁴ In the United States it is 1.39 per 1,000 for males and 1.12 for females.⁶⁵

From these tables, which deal with numbers of sufficient magnitude to reduce to a minimum the sources of gross errors, it is clear that, all along the line, pneumonic fever prevails to a considerably greater extent in males than in females.

It has been supposed that this greater prevalence of the disease in males depended upon the class of people furnishing the statistics. That this is not the case is proven by the returns from various populations. Thus amongst a purely agricultural people the proportion of deaths is 58.8 males to 41.2 females. Amongst a manufacturing class it is 54.5 to 45.5, and in largest cities it is 53.6 to 46.4, males and females, respectively.⁶⁶

In studying this subject statistically there are some points to which especial consideration should be accorded. Thus, if we confine our inquiries to the available statistics of *cases* we must draw our material largely from hospital reports. Now it is notorious that the two sexes do not seek admittance into these institutions in equal numbers, the proportion of males in the population from which they draw their patients being largely in excess of the females. It is clear, therefore, that if we confine ourselves to these figures we will be led into the error of attributing to males a much larger proportion of cases than really belongs to the sex.

On the contrary, if we turn our attention to the returns of *deaths*, the question arises whether the disease is equally fatal in males and females. According to most authorities and my own investigations the mortality is considerably greater in the latter than in the former sex. It follows, then, that if such statistics be employed the proportion of males will be shown too small.⁶⁷

RACE.

The various races of mankind are not attacked with the same frequency by pneumonic fever. The negro⁶⁸ is peculiarly subject to attacks of this

⁶⁴ Dinstl, *Österr. Zeit-schr. f. Prakt. Heilk.* Bd. viii, 1862. Reuf, *Heidell. Med. Ann.* Bd. ii, 1836. Tolmouch, *Ann. de Hyg.* T. xiv, p. 252, and others have not been able to notice any difference in the liability of the sexes to attacks of this disease.

malady, especially when removed from his native land. The average African's indolence, habits, mode of living, loss of sleep, debauchery, venereal excesses, cold sleeping rooms, exposure to night air and, to him, low range of temperature, etc., are conditions which certainly have an influence in causing an excessive prevalence in this race as seen in this country.

The functions of the skin in the negro are more extensive and important than in the Caucasian. It is more actively depurative and is to a greater extent supplementary to the lungs and liver—throwing off a great amount of moisture and carbonic acid—and external impressions which cause suppression of the perspiration are prone to be followed by pneumonic fever.

The disease is asthenic, rapidly exhaustive, attended with marked mental and physical prostration and is often latent and unsuspected. Copious effusion into the pleural sac, alveoli and bronchi is the rule. It frequently appears as an intercurrent affection—often without subjective symptoms.

During a series of years there occurred at the Memphis Marine Hospital 404 cases of disease amongst the white sailors, with 10 cases of pneumonic fever—.22 per cent.—whilst the blacks furnished 525 cases of all diseases, with 26 of pneumonic fever—5.0 per cent.⁶⁹ In the British Army this malady affords 20.2 and 33.3 cases per 1000 of force annually in whites and blacks respectively.⁷⁰ In 1880, in the Southern States⁷¹ pneumonic fever figured in the census returns one-half more in the case of the blacks than in the whites.

Pneumonic fever is very prevalent amongst the American Indians. In a population⁷² of 78,521 the death-rate was 2.65 per 1000 persons and it caused 7.4 per cent. of all deaths.⁷³ It is also common to the Esquimaux, in whom it is very fatal, assuming a low, adynamic course.

The Malays and the natives of Hindostan and Burmah are but little prone to attacks of this disease.⁷⁴ This is also true of the Chinese.⁷⁴

The malady is more prevalent in some branches of a race than in others. Thus it is the cause of a greater proportion of deaths in the Celt than in the Teuton.⁷⁵

RESIDENCE.

Where people congregate for residence, there, other things being equal, will pneumonic fever be found in the greatest proportion.⁷⁶ This fact

is shown in the following tables and statements:

TABLE XXVII.—SHOWING PREVALENCE OF PNEUMONIC FEVER IN RURAL AND URBAN DISTRICTS.

COUNTRY.	AUTHORITY.	Country.		Cities.		Excess in	
		Per 1000 Pop.	%	Per 1000 Pop.	%	Rate	City.

Switzerland	Sanders	1.50	3	1.71		.21	
Averages		1.21		1.62		.41	

In London, in 1838–39 there were reported 7,431 deaths from pneumonic fever, whilst the rural counties of Cornwall, Devonshire, Dorsetshire, Somersetshire and Wiltshire, with about the same aggregate population, returned, during the same years, but 3,446 deaths from the same cause, being in the proportion of 1000 urban to 463 rural. In these same years twenty-four town districts in England returned 15,062 deaths from this cause, whilst twelve country districts, having approximately the same population, returned only 6,218 deaths from the same cause, being in the proportion of 1000 urban to 413 rural.⁷⁷

It follows, as a reasonable conclusion, that if pneumonic fever is more prevalent in the towns than in the cities that, in general, it will be met with more frequently in the larger cities than in the smaller ones,⁷⁸ and this can be shown to be a fact.

TABLE XXVIII. SHOWING PREVALENCE OF PNEUMONIC FEVER IN CITIES ACCORDING TO SIZE.

Mortality.		
Population.	Cities No.	Per 1000 Pop.
Above 1,000,000	5	1.82
500,000 to 1,000,000	11	1.74
200,000 to 500,000	28	1.79
100,000 to 200,000	52	1.45
50,000 to 100,000	36	1.18
10,000 to 50,000	93	1.24
Total and average	225	1.38

Although pneumonic fever is comparatively infrequent in sparsely settled districts,⁷⁹ it there pursues a more acute course than in populous neighborhoods.

Domiciliary crowding is accompanied by an excessive prevalence of the disease.⁸⁰ Those who are ground down by the iron heel of poverty suffer far more than the wealthy.⁸¹

Those who go down to sea in ships are but little liable to attacks of this disease.⁸²

Thus of 24,000 sailors in the French navy only 175—7.3 per 1000—were attacked by pneumonic fever.⁸³ In the U. S. navy it is even less prevalent, being in 1880, 5.2, per 1000, and in 1881, 4.5 per 1000.⁸⁴

Soldiers are more liable to attacks of pneumonic fever than are civilians of the same age.⁸⁵ Thus in France the number of cases per 1000 of military age is 30, whilst in the French Army it is 39. Common soldiers suffer more than officers, and infantry more than cavalry.⁸⁶

In garrison they suffer more than when on the march, in peace than in war⁸⁷ and on land than at sea.⁸⁸ These facts are probably due to the fine weather, pure air and healthy condition of the troops, when a march, campaign or voyage is undertaken.

The inmates of prisons, asylums, monasteries are said to be more liable to attacks of this malady than persons enjoying their freedom,⁸⁹ but this is not borne out by my experience or investigations.

For many years I saw all the cases of illness occurring among 500 inmates of cloisters, and met with pneumonic fever only twice in eight years.

Addison⁹⁰ says that "it is somewhat singular that, as a general rule, pneumonia is a disease not often met in hospital wards." This statement does not agree with the statistics which I have adduced or the observations of physicians generally.⁹¹ Indeed I am convinced that the proportion is greater than in private practice.

RECURRENCE.

A person who has once had pneumonic fever is subsequently more liable to be attacked than one who has never experienced the disease.⁹²

Of 78 infantile cases analyzed by West, 31 had had previous attacks—21 twice, 4 thrice, 2 four times, and 4 several times. Ziemssen found that of 201 cases, 19 had had the disease previously—14 twice, 3 thrice, and 4 four times. Of 175 cases tabulated by Grisolle, 54 had had preceding attacks. Of 212 cases analyzed by Griesinger, 36 had had the disease before. Rush⁹³ has noticed three, four, five and eight attacks in the same individual, Paget seven, Chomel ten, Frank eleven, Kocher⁹⁴ eleven, Andral sixteen, and Rust⁹⁵ as many as twenty-eight. Of 252 cases reported by Doubleday⁹⁶ 12 had had previous attacks. Of my 498 cases 101 had had the disease previously—76 twice, 14 thrice, 5 four times, 1 six times, and 1 eight times. In quite a large number of patients treated for other maladies the history developed the fact that they had previously suffered from multiple attacks of pneumonic fever.

Children are peculiarly liable to multiple attacks, Juergensen recording the case of a girl four years of age, who had already had six attacks.

The intervals between the attacks may be more or less prolonged—varying from a few weeks to several years.⁹⁷ They are necessarily shorter in proportion to the frequency of recurrence. Ziemssen's⁹⁸ inquiries developed the curious fact that in some cases there is a tendency to recurrence at about the same time each year.

Thus in one case the first attack occurred Dec. 17, 1856, and the second Dec. 12, 1857. In another case the first attack occurred Aug. 8, 1856, and the second July 6, 1857. In yet another instance the first attack came on Jan. 28, 1856, the second Jan. 6, 1858, and the third Jan. 25, 1859.

Such coincidences have not been conspicuous in my list of cases.

Recurrence is oftenest noticed when the local lesion is in the left lung,⁹⁹ and the same lung is apt to be again and again affected,¹⁰⁰ although not necessarily in the same part.¹⁰¹

The persistent recurrences of pneumonic fever has been attributed to the gouty diathesis.¹⁰² In England, where gout, amongst the upper classes, is the national disease and the insignia of age and respectability, the occurrence of repeated attacks of this disease in subjects of this diathesis may be a frequent coincidence, but I venture the assertion that recurrent attacks occur with equal frequency in other lands where gout is almost unknown.

REPORTS FROM HOSPITALS.

SURGICAL CLINICS AT THE WESTERN
PENNSYLVANIA HOSPITAL BEFORE
THE STUDENTS OF THE WEST-
ERN PENNSYLVANIA MEDI-
CAL COLLEGE.

BY PROFESSOR J. B. MURDOCH,

SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL AND PRO-
FESSOR OF CLINICAL SURGERY IN THE WESTERN PENN-
SYLVANIA MEDICAL COLLEGE.[Reported by WILL. N. PRINGLE, M.D., a member of the Gradu-
ating Class.]*February 9, 1889.*

THE TREATMENT OF HÆMORRHOIDS.

I have a patient to show you to-day with that very prevalent disease, namely, hæmorrhoids. Now as you know there are two principal varieties of hæmorrhoids, the internal and the external, and those two varieties have their seats in the two plexuses of hæmorrhoidal veins. The inferior plexus is situated just within the sphincter ani, and empties its blood into the illiac veins, and then through the inferior vena cava to the heart. The superior plexus is situated about one inch above the inferior plexus, and empties its blood, via the portal system, into the liver, and thence through the vena cava to the heart. The causes of hæmorrhoids is the same as that of varicose veins in any other part of the body, and that is obstruction to the return circulation; this may result from various causes, as abdominal tumor, gravid uterus, constipation, impaction of fecal matter in the rectum, being constantly on the feet, together with many other states and conditions of the system. External piles are at first the same as internal piles, but from constant congestion and by being repeatedly forced down in defecation, they become as it were strangulated in the rectum and the blood becomes organized, into forming small tumors which sometimes appear as little tags, around the verge of the anus.

It is said that man is the only animal that is subject to piles, a penalty apparently for his being in the erect posture. The treatment is palliative and curative. The palliative treatment consists in removing obstructions to the return circulation and stimulating a torpid liver when this condition exists. A favorite laxative with me is that known as Van Buren's mixture which is as follows:

R. Magnesia sulphas,
Potassii bitartras,
Magnesia carbonas,
Sulphur sublimat, ʒʒ equal parts.

Mix et signa one heaping teaspoonful in water before breakfast.

This mixture, taken in this way, keeps the bowels in a softened and moistened condition and favors peristaltic action. The curative or

radical treatment consists in operative measures. In external piles where they appear as little tumors or tags, you may snip them off with the scissors, or a scalpel; there is very rarely any hæmorrhage, and when there is it is easily controlled, as the bleeding point is under your eye. Not so, however, with internal piles; in these the vessels may be large and not so readily accessible, and patients have been known to bleed to death before these vessels could be controlled. In dealing with this form of piles we use the clamp, the cautery, or the ligature. In using the clamp, the pile is caught at its base, between the jaws of the clamp, tightly compressed, then cut or shaved off, in front of the clamp, and the cut surface or stump seared with the actual cautery; this is Mr. Smith's operation, and the clamp is called Smith's clamp. Another and a more recent operation consists in injecting the pile with carbolic acid. This operation originated among men outside of the profession, or irregulars; it sometimes acts very effectually and with so little pain or inconvenience to the patient, that the regular profession are now giving it a trial. This is not the first case, either, in which the profession has received valuable hints from charlatans. Mr. Heaton's cure for hernia, by the use of white oak bark, originated in the same class of people, and the fact that we accept and use these hints, merely shows that we, as a class, are not bigoted, obstinate, nor old fogies, but are willing to accept any thing, from any source, that offers good to our patients.

The patient requires to be prepared for this operation, the bowels should be unloaded by a cathartic the day before, and an injection should thoroughly cleanse out the rectum a few hours before the operation; the external surface should also be thoroughly washed with soap and water. I propose to inject these piles to-day with carbolic acid and the solution I prefer consists of the following:

R. Ac. carb. ʒss.
Glycerine,)
Aqua,) ʒʒ ʒj. m

The needle is then made to pierce each pile and four or five drops of the solution left as near the centre of the pile as possible. In order to deaden the sensibility to pain which sometimes follows the injection of the acid, I will first inject ten or fifteen drops of a 4 per cent. solution of cocaine. After the injection of the cocaine, the needle is allowed to remain in the pile about two minutes, while the syringe is removed and filled with the acid solution, and again attached to the needle and the acid injected. Shortly after the injection of the acid the pile turns to a purplish or bluish color and becomes hard. A compress is applied over the anus retained by a T bandage, the patient is put to bed and given a quarter of a grain of morphia, and the pile soon shrivels up and dis-

appears. To-morrow the patient will be allowed to walk about the ward, and in a day or two can go about his business.

Some precautions are always advisable in doing this operation; after you have dilated the sphincter ani, and brought the piles into view, it is always well to pass a small sponge with a string attached into the rectum, to prevent feculent matter from coming down to interfere with the operation. It is also necessary for you to lubricate all the surrounding tissues, to protect them from any of the acid that may be dropped on them. I would also suggest that you do all as humanly as possible; do not cause your patient unnecessary pain. I think that surgeons get careless about this sometimes. I am sure that if it was their own case they would be more careful. As I said, this operation is only on trial yet. In my hands it has not yet yielded very brilliant results, and I do not believe that it is as efficient or as certain in its results as our old plan of operating.

POTTS' FRACTURE.

I have another case to show you, one of interest, and one that affords me an excellent opportunity to speak to you on the subject of Potts' fracture. This is an exceedingly common form of accident and one which you may be called on to treat during the first months of your practice. It consists of a fracture of the fibula two and one-half inches above the ankle joint, together with rupture of the internal lateral ligament and frequently the internal malleolus is fractured off and dislocated inward with the foot and astragalus. It is caused by a violent turning of the foot outward; the patient falls from a height, striking on the inner side of his foot; the foot is strongly everted and the entire weight of the body coming on the internal lateral ligament, it ruptures or fractures off the internal malleolus; the whole force is then directed against the external malleolus forcing it outward.

Now, the fibula you know, is attached to the tibia by means of the interosseous or tibio fibular ligament. With strong pressure forcing the lower end of the bone outward, the bone is made to act as a lever, with the ligament acting as a fulcrum, and the fibula gives way and is thrown against the tibia. The bones may be forced through the skin, constituting a compound fracture, and the joint may be thoroughly disorganized, making it a compound complicated fracture. There is increased mobility: the lower end of the tibia or the internal malleolus forms a prominent projection inward. At the seat of fracture of the fibula a depression exists, as there also is where the internal malleolus is fractured off; and you will see by looking at this patient's foot that the joint has a "spread" appearance. The object of treatment is to prevent the foot from remaining everted, the tibia and fibula must be made to

grasp the astragalus and then be retained in that position. For this purpose many splints and appliances have been devised. It is not sufficient that the foot be made straight, it must be held in an inverted position. In this hospital we use the plaster dressing, and I had intended to apply that dressing to this limb in your presence to-day, but as you see, the limb is too much swollen and congested, so we will defer that operation and show you a fractured humerus.

TREATMENT FOR FRACTURES OF THE HUMERUS.

We have a patient here who had his humerus fractured by direct violence on December 7. He remained in the hospital for about four weeks, when he went about his business. Shortly afterward when alighting from a moving car he had his arm twisted, refracturing his humerus at the same place by indirect violence. I would like to say a few words here in regard to the treatment of fractures of this bone. We more frequently have non-union of fractures in this, than in any other bone in the body, and especially if it be fractured about its middle, and this, I think, is from faulty treatment, from not retaining the fractured extremities in apposition. We may be able to reduce the fracture, and we almost always do; but do we retain it in position, do we immobilize it? I think that we frequently do not. The arm is an exceedingly difficult extremity to keep perfectly quiet; patients will move the arm more or less in spite of themselves. It has long been a rule in the treatment of fractures that the joint nearest a fracture be confined, or rendered immobile; this I consider good practice in the majority of cases, but I think there are exceptions to it, and the case of a fracture at the middle of the humerus, I think, is an exception to the rule; because, if the arm cannot be kept at rest and the elbow is firmly confined, then the motion must take place at the seat of fracture; therefore I do not fix the elbow, and I believe that to be the proper treatment. This, however, only pertains to fractures of the shaft. When the fracture is through, or near the condyles, then, of course, it is preëminently necessary to fix the elbow. Acting on my convictions therefore, I propose to apply to this fracture a short anterior and a short posterior splint, and a shoulder cap.

February 23, 1889.

GUNSHOT-WOUND IN THE LEG.

I have a patient here to show you to-day, a boy of 14 years of age, who two weeks ago shot himself in the leg below the knee with a small rifle, known as a target, or Flobert rifle. He at once applied to a physician, who was evidently a sensible man, inasmuch he at once endeavored to render the wound antiseptic; but who again was not as sensible as he might have been, because he probed the wound. He did not find the ball

either, a usual result in such cases. The boy then came to the hospital and was not probed here, and the ball still remains in his leg; and as you see he does not suffer any inconvenience from it, he walks well and feels no pain. This should be a very instructive case to you, because it will serve to illustrate the folly of probing for bullets, in gun-shot injuries. A great surgeon has divided gun-shot wounds into two great classes, namely those that have been fingered, and those that have not been fingered. The greatest damage that a bullet can do is done in its passage through the body, it being surrounded by fire from the discharge of the powder and its rapid flight through the air, have rendered it aseptic, and the wound it inflicts will therefore be aseptic, and you know that the tissues are very tolerant of metallic substances; you know this from seeing us day after day inserting metallic sutures into almost any and every tissue of the body. You also know that men have carried needles, bullets and other metallic substances in their bodies for years without inconvenience. It is said that Andrew Jackson carried a bullet, received in a duel, in his body for twenty years, with little or no pain or inconvenience. You know therefore that bullets are in many cases aseptic, and innocuous, and that by probing the wound with a foul finger, or a dirty probe, you may carry germs into the wound, thereby rendering the wound septic and doing your patient irreparable damage. There are, however, cases in which it becomes absolutely necessary to remove the bullet, as where it rests in a vital part, or against a nerve. And where you do probe a wound, you should do it strictly, antiseptically, cleanse the surrounding parts, cleanse your hands and probes in antiseptic solutions and never pass a probe into a gun-shot wound in search of a bullet until you have everything in readiness to remove the ball if your probe should come in contact with it. Otherwise the information gained by probing will be lost, and you will have done an unwise act. Never do anything, until you are prepared to do everything, is a good motto in these cases.

Dr. Park, the distinguished Buffalo surgeon, relates a case of a young man, a laborer in a freight yard, being accidentally shot in the region of the nipple, a number of surgeons gathered at once and began probing the wound. When Dr. Park arrived he was assured by one of the surgeons, (who triumphantly exhibited his probe), that he had passed his probe into the man's body to the extent of three or four inches. He was asked if he found the bullet, and replied he did not. Dr. Park then suggested that they make a thorough examination of the body, and on turning the man over, they found another wound, at the lower angle of the scapula; the wound of exit of the bullet. And these surgeons had been

diligently probing for a bullet that was not in the man's body, but that had gone flying far out in the freight yard. And suppose they had succeeded in locating the ball in the body, their information could have availed them nothing, because they were not prepared to remove it. Dr. Park relates another case, of a surgeon passing a probe into a man's brain, in search of a bullet, when the information could have been of no value whatever to him, because he was not prepared to remove it, and he was already aware that it was in the brain, because brain substance was oozing from the wound behind the ear. I hope now that you all see the folly of such proceedings and not only the folly but the danger. You not only render the wound septic, but you may disturb clots and cause hæmorrhage, which may cost your patient his life. Now let me tell you the proper thing to do in these cases. First occlude the wound with some antiseptic material, cotton wool or soft cloth saturated in any antiseptic fluid, will answer the purpose very well, then if it becomes necessary to remove the ball, transport your patient to a place where you can have all the requirements and appliances for removing the ball before you begin to probe, and be sure that the ball is still in the patient's body before you do any unnecessary probing. Also bear in mind that bullets almost always deviate or are deflected from their course; do not try to force your probe in any direction, but allow it to follow the course of the wound slowly and carefully, which it will sometimes do almost by its own weight.

MEDICAL PROGRESS.

ON DIAPHORESIS IN SYPHILIS.—DR. RADESTOCK, of Geithain (Saxony), again calls attention to this subject in an article which recently appeared in the *Therapeutische Monatshefte*, where he mentions the use of decoctions from lignum vitæ, divers infusions, mercurial fumigations, and among others, the thermal springs at Aix-la-Chapelle and Wiesbaden. Syphilis would not improve by the sole use of sudorific means, without the help of classical treatment, but their combination with mercury or iodide of potassium appears of undeniable value, inasmuch, probably, as it favors the elimination of the specific poisons, the same as sweats in fevers or infectious diseases. We notice, for instance, that in people who perspire a great deal, as in soldiers or stokers, roseola does not last as long as in others, and even small-pox is less serious. Radestock's method consists in prescribing a hot bath of about 30 minutes duration, until the skin becomes red. To continue the perspiration tea or hot infusions are given, or subcutaneous injections of 2 centigr. of chlor-

hydrate of pilocarpine daily, as does Lewin in the Berlin Charité for medium forms of syphilis. Also vapor baths or hot-air baths might be used, which could be given while the patient is in bed, with the help of a stove invented by Dr. Friedler, and used by him in the Dresden Hospital. At first, and in grave cases, Radestock bathes his patients every day; later on, when all manifestations have disappeared, once a week; after that at greater intervals.—*Journal de Médecine de Paris*, May 5, 1889.

A NEW RAPID PROCESS OF COLORING THE TUBERCLE BACILLUS.—MR. GABRIEL ROUX communicates a new method, by Martin Herman, of Liège, which is as follows: After the cover-glass preparations have been made as usual they are dipped for one minute in the following mixture: 1. Crystal violet, 1 gr., alcohol of 95°, 30 c. c., (a few drops). 2. Carbonate of ammonia, 1 gr., distilled water, 100 c. c. (a few cubic centimetres), which is kept at the boiling point during the entire period of immersion. Then wash in water and discolor for four or five seconds in a water solution of nitric acid, 1:10 for sputa and 1:4 for sections. Then wash in alcohol of 95 per cent. and examine immediately. If a double coloring is desired, immerse for one to two minutes in the following solution: Eosine 1 grm., alcohol of 60° 100 c. c. The great merit of this new process is that it is trustworthy, and requires no especial degree of skill; it is not any more rapid, nor any more brilliant in its results than its immediate predecessors, but it is more practical.—*La Province Médicale*, May 11, 1889.

CYSTIC DISEASE OF KIDNEY DIAGNOSED DURING LIFE.—At a recent meeting of the Glasgow Pathological and Clinical Society, DR. DAVID NEWMAN showed preparations from a case of cystic degeneration of the kidney diagnosed during life, which presented exceptional symptoms. The patient, a man æt. 46, suffered from dyspeptic symptoms, headache, giddiness, persistent renal pain, and hæmaturia. The pain was first felt on the right side, and, although severe, was unattended by hæmaturia. Eleven months subsequently pain developed in the left side, with a slight tinge of blood in the urine. When he came under Dr. Newman's care the symptoms led to the suspicion of malignant tumor of the kidney; but, on rough examination, it was found that the urine contained a larger quantity of albumen than could be accounted for by the hæmaturia alone, and for the purpose of ascertaining the relative amount of hæmoglobin and albumen a careful analysis of the urine was made on twelve occasions. When the albuminuria was due to the presence of blood, the ratio of hæmoglobin to albumen was as 1.6 to 1, but as shown by the analysis, the average ratio in the twelve specimens was

as 1 to 3.6, that is to say, not more than a fifth part of the albumen present in the urine could be attributed to the blood. The microscope showed hyaline and tube casts; by obtaining separate samples of urine from the two ureters, it was ascertained that the blood came from the left kidney only. Physical examination revealed distinct swellings in both renal regions, which steadily increased in size. There was also evidence of hypertrophy of the left ventricle of the heart and increased arterial tension. The case illustrated the value of detailed estimation of the quantities of albumen and hæmoglobin in cases of hæmaturia, and also the benefits to be derived from an examination of the separate specimens of urine from each kidney. In most cases of cystic disease the symptoms were those of chronic Bright's disease, with swellings in the groins superadded; not infrequently this disease had been confounded with ovarian cystoma, and kidneys had been removed under mistaken diagnosis. In respect to surgical treatment nothing should be done. On account of the wide distribution and multilocular character of the cysts, no benefit could be expected from nephrotomy, while nephrectomy was contra-indicated, because the disease was not only bilateral, but the kidneys were the seat of chronic interstitial nephritis, so that if one were removed, the remaining one was unable to do the additional work thrown upon it. Of 16 cases of nephrectomy for cystic degeneration which Dr. Newman had collected, 6 died, 2 from peritonitis, 1 from uræmia, 2 from shock and collapse, 1 from oedema of the lungs, while 10 recovered, thus giving a mortality of 37.5 per cent.—*The British Medical Journal*, May 25, 1889.

MURMURS IN THORACIC VESSELS FROM EFFUSION OF FLUID INTO PLEURA.—DR. SIDNEY PHILLIPS, in a series of papers just published in *The Lancet*, says: A murmur is sometimes produced in the large vessels of the thorax from the rapid effusion of fluid into the pleura. The following case affords an example of this. A male patient who had been ill in bed for a month with chest symptoms, who had been repeatedly examined by several physicians, and in whom it was certain that no murmurs existed, after pleuritic friction had been observed for some days, was found to have the signs of a large accumulation of fluid in the left pleural cavity. The effusion was very rapid, the dulness in a few hours rising to the level of the spine of the scapula. The apex of the heart was felt plainly in the right axilla, and there was evidence of considerable compression of the lung. Simultaneously a murmur of great intensity was developed; it was heard beneath the sternum opposite the second and third rib cartilages, and could be traced obliquely to the left behind that bone in the second and third left intercostal spaces. Supervening suddenly as it did.

and coincidently with the rapid effusion into the pleura, it could hardly have been the result of anything but traction upon and stretching of one of the large vessels in the thorax, and from its position and direction appeared to be produced in the pulmonary artery. That this was so was borne out by the fact that after several aspirations of fluid the chest was eventually incised, and as the heart returned to its position the murmur entirely disappeared. I have not found any definite allusion in any of the works I have been able to consult of murmurs in the arteries produced in this way, but the recognition might be important, for in cases where the patient had by previous observation been known to be free from murmur such a bruit as that heard might be readily taken in conjunction with the other physical signs for evidence of aneurism or intra-thoracic tumor.

PURE CULTURE OF THE TETANUS BACILLUS OF NICOLAÏER.—M. KITASATO, of Tokio, Japan, recalls the discovery of the tetanus bacillus by Nicolaïer, its presence in the soil, its existence in men afflicted with tetanus (Rosenbach), and claims that so far it has not been possible to obtain pure cultures of this bacillus.

A young soldier died from tetanus. In the pus of his wound the bacillus of Nicolaïer was found. Inoculation of this pus upon mice produced in the latter genuine tetanus, and the characteristic bacillus was found in them. But cultivation failed, and only mixed cultures were obtained. In examining these more closely Kitasato found by the side of Nicolaïer's bacillus, three kinds of anaerobic microbes, and seven kinds of aerobic microbes; neither the former nor the latter could cause tetanus.

The tetanus bacillus is a genuine anaerobic bacillus. After having discovered that the mixed cultures obtained from the tetanus pus contained the largest number of Nicolaïer's bacilli when the oven is kept at 36° , Kitasato exposed them for some time to this temperature, and then, the cultures being in full development, he placed them for a short time in a water-bath at 80° . This temperature kills the adventitious microbes, but lets the spores of the tetanus bacillus live. After this partial sterilization the plate-culture was kept in a temperature of from 18° to 21° , in an atmosphere filled with hydrogen. In this way he succeeded in obtaining a pure culture of Nicolaïer's bacillus, with which he was able to produce tetanus in rats, guinea-pigs, and mice. The tetanus always begins to spread from the point of inoculation. The parts surrounding the latter are always the first to be affected with tetanus.

Nicolaïer's bacillus bears heat well. It is necessary to expose it to a temperature of 100° for five minutes in order to kill it. A solution of phenic acid of 5 per cent. did not destroy at the end of ten minutes. It is remarkable that the

bacilli disappeared rapidly from the blood. It seems that they develop ptomaines there. This must be established by future experiments.—*La Semaine Médicale*, No. 18, 1889.

A NEW PTOMAINE.—HOFFA, of Würzburg, wishes a distinction made between septic intoxication and septic infection. When numerous microorganisms are found in the blood, one may speak of a septic infection. But in other microbial affections the microbes are not found in great numbers, on the contrary, they are very rare and it is almost by accident that they are found. In these cases where the bacteria disappear so rapidly from the organism, they are killed by the ptomaines which they produce, and of which various authors (v. Bergmann, Brieger, and others) have already shown us typical forms.

Hoffa repeated the experiments of Brieger. He intoxicated a rabbit with bacilli of septicæmia of mice, and prepared it according to Brieger's process, carefully excluding the urinary organs and alimentary canal from the carcass to be examined. In this way he succeeded in isolating a base which was recognized as methylguanidine ($C_2H_7N_3$), *i. e.*, as the same poison which Brieger and Bochlisch obtained with the bacilli of Finkler-Prior.

As methylguanidine originates from the oxidation of creatine, Hoffa subjected a healthy rabbit to a chemical analysis, treating it in the same way as the one infected with bacilli, and no traces of methylguanidine could be found. This base is a strong poison, of which 0.20 centigr. suffice to kill a rabbit. It is, therefore, methylguanidine which is produced by the bacilli of septicæmia, and which kills the animals. From the bacilli of rats he isolated a toxic base, of which $C_3H_8N_2$ is the formula; it is, therefore, a principle differing from methylguanidine.—*La Semaine Médicale*, No. 18, 1889.

ON COLD ABSCESSSES AFTER MALARIA.—DE SABOIA (Rio de Janeiro), in the "Bull. et mém. de la soc. de chir. de Paris," T. xiv, p. 141, calls attention to a very rare exception to the rule that most cold abscesses are of tuberculous origin. He observed in 4 cases cold abscesses after acute malarial infection. After a severe malarial fever in the different patients a large number of abscesses formed within 12–48 hours, differing in size from almonds to considerable volume, without any fever, pain, or reddening of the skin; only slight tenderness to pressure indicated the formation of a new pus center. In one patient 28 abscesses had to be opened within a few weeks. A cure resulted in every case. Bacteriological examination proved the existence in the pus of the malarial microbes described by Mardrinfava and Celli. The possibility of tuberculosis was absolutely excluded.—*Centralblatt für Chirurgie*, May 11, 1889.

Address

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, JUNE 22, 1889.

THE NEED OF SANITARY LEGISLATION.

It is an accepted fact that the health of a Nation is paramount to its commercial prosperity, and that when human life is imperiled thereby, even the wheels of commerce must stop. It is also an axiom that the demands of the public good are paramount to individual interests. The practical application of restraints upon business for the protection of health is often severe in its effects upon individual interests, and nothing but the strong arm of the law can make such restraints operative. Hence the necessity of municipal and of State legislation for the preservation and protection of the public health. The intelligence of the American people is such, and such their estimate of human life, that they need only to be advised as to the best means of exercising sanitary control, to strongly uphold all legitimate legislation in this direction. In fact, the progress in matters of sanitary legislation during the last few years has been in the highest degree commendable.

Until a comparatively recent period the control of matters affecting the public health was vested in the police legislation of our larger cities. More recently nearly every incorporated city in the Union has more or less perfectly developed its system of sanitary supervision. During the last fifteen years State after State has taken this matter in hand, until now, instead of a half dozen, at least thirty of the States of this Commonwealth have organized their State Boards of Health. So far as we are able to learn, the power vested in

these several Boards has been exercised, in the main, with eminent discretion. In each individual city and in each State, even in emergencies, the exercise of the powers thus vested seem ample to meet ordinary necessities.

But there are conditions in which the limitations imposed upon cities and even upon States are such as to render necessary a supervising control which reaches beyond the city, beyond the State, and can only be exercised by the authority and in the name of the Nation. We do not propose to enter upon the discussion of local or State rights as applied to the control of epidemics and infectious diseases, but we think it is manifest to all candid men, that emergencies are liable to occur at any time wherein adjacent States may find their interests conflicting, and where want of concerted action may render sanitary restrictions practically inoperative. The peril to the body politic, when a pestilence is traveling across the continent, is not limited to cities or by States. It is national in its relations, and the law that cannot be operative for its control, by reason of municipal or State limitations, is unequal to the emergency. Hence the necessity of National legislation and maintenance of a National Board of Health.

In this country power is so largely vested in the States that it becomes a matter of most careful consideration as to the proper adjustment of responsibilities and control, but we are confident that the time is at hand when such adjustments should be made. In the day of severe calamity, we shall not have time for the settlement of questions of such moment.

It is manifest that National legislation alone can meet the needs when National interests are involved, and the importance of the subject is such that the wisest measures should be thoroughly matured and made operative by appropriate legislation. Possibly a Bureau, in connection with one of the State Departments, could best assume the surveillance of the public health; of International and inter-State quarantine, of vital statistics, and of the sanitary conditions of National thoroughfares, and thus render an invaluable service to the Nation.

But the Department of Public Health should be removed as far as possible from the vicissitudes incident to politics, and those who by reason of talent, culture and fitness may be called to fill the responsible positions connected with this depart-

ment, should be so assured of a permanency as to warrant the sacrifices that such appointment might demand. The subject is not new; nor should it be allowed to grow *old* while there is such manifest need of further National legislation for the perfection of our sanitary laws.

MASSAGE IN GYNECOLOGICAL PRACTICE.

Resuming the discussion of this subject at the point where it closed in the last issue, we desire to consider, *first*, the method of treatment of uterine displacement adopted by Brandt.

Brandt's most original method of treatment, and the one indeed whose invention is no doubt rightly ascribed to him, is termed "elevation of the uterus" (German, *Uterushebung*; Swedish, *Lyftrörelser*), which may be briefly described as practiced by him in prolapsus uteri. The patient lies on a low, short, reclining chair. The physician begins by replacing the uterus, which he then supports by pressure on the cervix. He then indicates to an assistant the position of the fundus. The assistant lays his outspread hands upon the lower part of the abdomen and makes equable pressure in a backward and upward direction, taking care not to displace the uterus. This manœuvre is repeated thrice, deeper pressure being made each time in the direction of the inguinal region. The assistant then holding his hands in a strongly supinated position, lays the tips of his fingers on the abdomen close to the edge of the symphysis and bending over the patient until his face approaches hers, he lays both hands quite flat on the patient's abdomen (one at either side of the physician's hands) and pushing the abdominal walls before him seeks to press deep down upon the cervix, taking care to keep close to the posterior surface of the symphysis. The physician next removes his external hand, while the assistant seizes the uterus from before and a little to one side and endeavors to lift it in an upward and forward direction, succeeding in which he then slowly and cautiously allows it to glide from his hands.

The height to which the uterus can be raised, depends upon the extent of relaxation of its ligaments and the degree of vaginal collapse. The uterus should be only moderately elevated at first; later on it should, in some cases, be raised to the level of the umbilicus. The uterus should be

elevated in this manner three times, with short intervals, at each sitting; after which massage of the uterus, Douglas' folds and the parametrium must be practiced. Contraindications are every acute and subacute inflammation of the pelvic organs, as well as the presence of an exudate. In prolapse the object of treatment is more quickly attained if the patient (at least in the early part of the treatment) keeps in bed and if the elevation of the uterus be practiced twice per diem; otherwise much of the results may be lost.

The next measure to be adopted, is that of pressure made a few times upon the pudendal, hypogastric and solar nerves. The object of this is to abolish all unpleasant sensations and prevent lascivious sensations.

Next in order is the forced abduction of the knees against muscular action exercised by the patient. This is regarded by Brandt and his followers, as a potent means of strengthening the pelvic floor; for the pelvic diaphragm (and especially the levator ani) is thereby excited to contraction whereby the muscular structures are gradually strengthened.

Finally, we have the stroking of the back and the tapping of the lumbar and sacral regions. The former is practiced by holding the hands together and making with the ulnar border of the little fingers short rapid strokes at either side of the spinal column from the neck to the loins and back again. The tapping of the lumbar and sacral regions is accomplished by means of the the closed hand, five strokes being made twice on either side of the lumbar vertebræ and seven strokes twice repeated on either side of the sacrum. These taps are to be made from the wrist joint and not from the elbow.

In regard to Brandt's treatment as applied to the various forms of pelvic exudates, it may be said to offer most available and valuable aid to the deplorably limited therapeutics of this department of gynecology. One writer (Dr. A. Winawer, *Centr. für Gynäkologie*, Dec. 29, 1888) who has found it most useful as an adjuvant to the diagnosis of tubal tumors, expresses himself as follows: "In cases where the tube is embedded in knotty masses of exudate and cannot be palpated even in narcosis, massage enables us to secure almost ideal relations for the examination; for when the abdominal walls are not too thick, all the pelvic organs can be palpated because, 1st,

after massage the abdominal walls are relaxed, yeilding and non-sensitive, and 2d, the knotty para- and perimetritic masses, adhesions of the ovaries, etc., are dissipated, so that the parametrium becomes elastic and painless. In this wise a diagnosis of salpingitis may often be made where otherwise no definite results could be obtained even during narcosis, and where there was, perhaps, no suspicion of tubal diseases.

Such, in outline, is the Brandt method of gymnastic massage. Of the inventor and his method we find, for the most part, extremely flattering accounts, particularly in the German current literature. Prof. Schaüta, for instance, says that "Brandt is a complete master of gynecological diagnosis. I was astonished at the minuteness and accuracy of his diagnosis."

On the other hand we have, naturally enough, unfavorable reports and accounts of unsuccessful cases treated by Brandt's methods. It is unnecessary, of course, in connection with a comparatively novel and strange method of cure to point out the causes of failure; but it should be observed that Brandt himself is adapted both by nature and art for the successful pursuit of his methods. He is endowed with great muscular strength, and has an unusually powerful hand with fingers of exceptional length.

It has been objected to Brandt's methods, that they are rude and harsh; but those who have seen him at work and who have had the best opportunities to judge, do not seem to so regard them. Other objections are the length of time required in the manipulations, which will of course prevent many a busy practitioner from applying the treatment which, nevertheless, cannot readily be relegated to assistants; for all are agreed that the greatest diagnostic skill is an absolute prerequisite to successful practice in this line.

It may readily be understood that the treatment is disagreeable alike to patient and practitioner; but it is to be remembered that some of the greatest triumphs have been witnessed in cases that had proved not amenable to any other forms of treatment, short of radical operations of a surgical nature.

If female gynecologists shall prove to have the necessary physical requirements for the successful employment of the methods in question, it will doubtless afford them a wide and profitable field of useful labor.

EDITORIAL NOTES.

HOME.

THE AMERICAN EDITORS' MEETING.—Our editorial confrères are reminded that the annual meeting of the American Medical Editors' Association will be held in the Casino, Newport, R. I., on the Monday evening preceding the meeting of the American Medical Association. The title of the President's Address will be "Our Duties as Journalists and the Reforms which we should Persistently Advocate." This meeting is open to every editor or member of the editorial staff of any regular medical journal in the United States and Canada.

A CASTOR OIL TRUST is being formed, and the preliminary work has been completed. There are seven castor oil mills in the country and the business is profitable. The mills to go into the combination are the Collier and Brown and Kansas, of St. Louis; the Belleville Oil Co., of Belleville, Ill.; Baker and Burke, of New York, and a concern at Memphis. There has been a pool in existence for years, but the business is so profitable that new capital is finding its way in, and the object of the trust is to regulate competition and control the outputs.

DR. H. W. ROSE, member of the Rhode Island State Board of Health has been succeeded by Dr. Herbert J. Pomeroy.

THE PHILADELPHIA MEDICAL MISSION treated 3,220 cases last year, and held 1,017 meetings.

DR. JEROME COCHRANE, State Health Officer of Alabama, has been making a tour of investigation through South Florida and Havana, and reports that he found very few cases of yellow fever at Havana, and only one case in Florida.

DIPHTHERIA.—Dr. John Irving, in the *British Medical Journal*, supports the view that "huge collections of decaying vegetable matter," such as stable manure, may, by disturbance, generate the disease, and cites several cases to prove his assertion.

THE COMMITTEE OF ARRANGEMENTS.—The Association were exceedingly fortunate in the selection of Dr. H. R. Storer, as Chairman of the Committee of Arrangements. The Committee are also indefatigable in their efforts to formulate such plans as will inure to the comfort and entertainment of the members of the Association.

The *Newport Observer* says: "They (the Committee) have had much to contend with, but it looks now as if hereafter there will be smooth sailing. Every one will hope so, and also hope that their efforts may be crowned with success."

THE DEARBORN OBSERVATORY, recently erected at Evanston, Ill., in connection with the new Astronomical Department of the Northwestern University, and containing the great equatorial, known as the Dearborn telescope, was dedicated last Wednesday with appropriate ceremonies. The building cost \$25,000, and was donated by Mr. James B. Hobbs, of Chicago.

FOREIGN.

THE JUBILEE MEETING of the Irish Medical Association was held in the College of Surgeons at Dublin, on the 3d inst.

THE *British Medical Journal* in its issue of June 1, presented its readers with a fine engraving of the statue of Queen Victoria recently unveiled by the Prince of Wales in the Medical Examination Hall on the Thames Embankment.

A TYPHOID COMMISSION IN INDIA.—A commission has been appointed to inquire into the causes of the excessive prevalence of enteric fever among young European officers and soldiers. At present, there appears a consensus of opinion to the effect that sewage contamination is the *fons et origo* of the mischief.

SMALL-POX IN INDIA.—A serious outbreak of this dread disease is reported from Belgaum. There are 120 cases, and the vaccinators are hard at work.

A NEW HOSPITAL FOR BOMBAY.—The foundation stone of the Bomanji Edulji Allibless Obstetric Hospital was recently laid by the Governor. Dr. Edith Pechey is to preside over the destinies of this new hospital.

THE ROYAL COLLEGE OF SURGEONS AND ITS MEMBERS.—The branches of the British Medical Association are supporting the demands of the members for reform by passing the following resolutions:

1. "That this meeting sympathizes with the desire of the Royal College of Surgeons of England to take part in the management of the affairs of the College."
2. "That this meeting strongly approves of the reform of the Royal College of Surgeons of England."

The *Provincial Medical Journal* advises the

members not to allow the resolutions to remain a dead letter, but to seek the coöperation of Members of Parliament in their respective districts.

HOSPITAL FOR MEDICAL STUDENTS AT VIENNA.—*Le Progrès Médical* states that a society has been formed in Vienna to provide for the comfort of students who are ill. A hospital is about to be established for their accommodation.

AN INTERNATIONAL CONGRESS OF THERAPEUTICS AND MATERIA MEDICA will be held in Paris, from August 1 to 5. It is open to all medical men, chemists and veterinary surgeons who send in their names and a fee of ten francs. There will be two Sections—one devoted to therapeutics, the other to materia medica. Amongst other questions the following are set down for discussion: 1. Antithermia and analgesic remedies. 2. The antiseptics best adapted for each species of pathogenic microbe. 3. Cardiac tonics. 4. New vegetable drugs recently introduced as therapeutic agents. 5. Uniformity of weights and measures employed in formulæ, and the utility of an international pharmacopœia.

THE PERILS OF BOOK REVIEWING were exemplified in a suit brought in a London court about a month ago, against the publishing firm of MacMillan & Co., for an alleged libel consisting of a review of Dr. Herbert Tibbits' work on "Massage and Allied Methods of Treatment" which appeared in *Nature*. The review was a caustic one, and in it occurred this sentence: "Any one even slightly acquainted with the subject will at once perceive that its writer, while professing to teach massage, has not mastered the first principles of the subject." The plaintiff claimed \$5,000 damages. The jury awarded him one farthing; and the judge refused him his costs.

THE SANITARY CONDITION OF NAPLES.—Active measures were inaugurated last Saturday, in which the King and Queen of Italy assisted, for improving the sanitary condition of Naples. The poorest districts of the city, where the cholera epidemic of 1888 made such ravages, will be thoroughly renovated. Seventeen thousand houses will be demolished, new streets erected, and the main street will intersect the district which now contains the most pestilential dwellings. It will take ten years to complete the work.

ASSOCIATION NEWS.

Notice to Exhibitors. Correction of Errors.

In THE JOURNAL of June 1st, page 783, there was an inadvertent use of a circular copy containing errors and which was superseded many weeks ago. If our Committee had been advised that there was to be a publication of the matter in the pages of THE JOURNAL we would have provided correct copy. In the document as published "\$19.00" should be made \$23.75, and "\$20.00" should be \$25.00.

C. A. BRACKETT,
E. P. ROBINSON,
Sub-Committee on Exhibits.

SOCIETY PROCEEDINGS.

Medical Society of the District of Columbia.

Stated Meeting, January 30, 1889.

THE PRESIDENT, CHARLES E. HAGNER, M.D.,
IN THE CHAIR.

DR. A. A. HOELING reported the following :

1. GUN-SHOT WOUND OF THE SPHENOID BONE ;
CASE AND SPECIMEN. 2. GALL-STONES.

Dr. Hoehling asked that the stones be referred to the Committee on Microscopy, as he was not certain whether they were gall-stones or concretions formed by the olive oil which the patient had taken. There being no objection the stones were referred.

DR. J. FORD THOMPSON : The case of gun-shot wound had been thoroughly reported, and there was little left for him to say, unless he opened the whole subject of gun-shot wounds, which he did not propose to do. He had had several similar cases, but death had been almost instantaneous. His last case was that of a young man on 13th street, who put the pistol in his mouth and death was immediate. Whenever the weapon is put into the mouth and fired it is not good surgery to explore the wound inflicted.

DR. LLEWELLYN ELIOT read a paper entitled
THE DIAGNOSIS OF PREGNANCY IN THE
EARLY MONTHS.

(See page 867.)

DR. A. H. HOEHLING reported

A CASE OF GUN-SHOT WOUND OF THE SKULL
MADE WITH SUICIDAL INTENT.

On December 16, 1888, there was admitted to this hospital, John H. L., a private in the U. S. Marine Corps, aged 42 years, native of Pennsylvania ; enlisted in Washington, D. C., on Dec. 7, 1888, for the third time.

Diagnosis.—Vulnus sclopetarium.

Origin.—Self-inflicted, and therefore not in the line of duty. The patient was discharged on the expiration of his second term of enlistment, about twenty hours before he reenlisted, as above stated. He had been on duty at League Island, Philadelphia, and his discharge took place there. He went on a spree and was robbed of the savings of five years while intoxicated, so he came here to begin life again as a private, having last been a sergeant. His descriptive list states that he had slight cardiac hypertrophy, and we found a small goitre, with decided exophthalmos, which latter was noticed by others before he shot himself. He had never been sociable with his messmates, but had one or two intimate friends among them, and was regarded as a good soldier, faithful on duty. He admits having carried the cartridge which he used for over two years in his pocket, with some vague notion, probably not well defined to himself. There is a rumor that he once jumped overboard, but I have not traced it to confirmation. He attributes his present attempt to mental depression consequent on the abuse of liquor, and the loss of all of his money, about \$250, for which he stood many a weary watch on board ship in distant seas, and amid the swamps of the League Island Navy Yard. At the latter place he was much exposed to malaria, and had there suffered from the same. On admission to the hospital, at 8:15 o'clock, A.M., the patient was in a state of profound shock, pulse rapid and almost imperceptible at the wrist ; respiration slow and labored ; surface cold and blanched. Blood was oozing from his nose and mouth, and he had the appearance of having lost considerable blood. Whiskey, as well as ammonia, were at once given by the mouth and hypodermically, also ergotine, atropia sulph. et morphia sulph. hypodermically ; ice was placed in his wounded mouth and hot bricks to his surface, to produce reaction, which latter was also hastened by hypoderms of sulphate of sparteine, and carbonate of ammonia by the mouth. In about an hour the patient had revived sufficiently to allow an examination of the injury. He said that he had used a Springfield rifle, charged with a " practice cartridge," which contained 5 grains of powder and will carry 100 feet with precision. In addition to the ball already in the metallic cartridge he placed two more bullets in it ; he then fastened a loop to the trigger, put the muzzle in his mouth, and with his foot in the loop fired the gun off.

Dr. H. T. Percy, U. S. Navy, who was the patient's immediate medical attendant, on examining the mouth found a penetrating wound in the median line of the roof of the mouth, $1\frac{1}{4}$ inch in length, involving the hard and soft palates and extending through the posterior portion of the septum narium. The four upper incisor teeth had been knocked out and the gums back of their

alveoli torn up for the distance of $\frac{3}{8}$ of an inch; the dorsum of the tongue was slightly lacerated. As he had already been probed, without success, and hæmorrhage was feared, because of the proximity of the wound to the internal carotid arteries, the probing was not then repeated. There was not a symptom indicating injury involving the brain at this time, nor for twelve days more, so it was supposed that the bullets must have been stopped by the thick bone of the basilar process of the occipital, the amount of powder used having been too small to drive the lead through. The oozing of blood had now become slight, his respiration remained labored, phonation very imperfect, mind fairly rational, but a little cloudy. At 3 o'clock, P.M., reaction was progressing slowly, hæmorrhage under control; considerable trouble in swallowing, the food passing up into his nose; a good deal of œdema of the soft palate; can only speak in a whisper.

Treatment of a sustaining character; milk and whiskey given both by the mouth and by enema, ice kept in his mouth to retard local inflammation, as œdema of the glottis was feared. The wet condition of mouth and throat, however, had prevented much burning from the sudden flame, just as one can place a wet hand in a flame for an instant with impunity. I am surprised that the excitement of committing suicide did not dry up his salivary glands, as we know the emotion of fear will do, but perhaps he was not afraid; at all events his tissues did not appear to be much damaged by fire and the œdema of the velum pendulum palati was due to the contusion and wounds caused by the explosion and the projectiles. In the evening his temperature was taken and found to be normal.

December 17th. Patient passed a restless night; deglutition very difficult, respiration labored, owing to swelling of the soft tissues around the glottis. Mouth and nose sprayed with solution of boracic acid; hot flannels to outside of throat; ice in mouth; morphia sulph. hypodermically *pro re nata*; diet: milk, eggs, and milk-punch. Evening: temperature 99.4° F.; he had quinia sulph., 0.60, at 4 o'clock, P.M.

December 18th. Rested better last night; less difficulty in swallowing and breathing; discharge from nose and mouth very offensive, for which used solution of sodii chlorinate, with sponge and atomizer. Apparently doing well, continue general treatment already indicated as to diet and medicines.

December 20th. Morning temperature 101.8° F. Evening temperature 103° F. In other respects the patient appears to be doing well. He swallows with ease, respiration not materially affected, mind clear, speech improved; considerable offensive discharge from the nose. Treatment: supporting; cleansing and disinfection of the wound and its vicinity; ice *ad libitum*, as he is fond of

it, and morphia sulph. hypodermically *pro re nata*.

December 25th. Doing well, apparently; range of temperature has been from 99.6° to 101.6° F. Discharge from mouth diminished, but still offensive, and smells like necrosed bone; the wound of soft parts of the palate has a healthy look, the slough having been thrown off; the wound of tongue and gum healing kindly; tongue coated with a brownish fur; fever, of septic origin, continues. Continue general treatment as before.

December 28th. Condition about the same; fever higher at times than at last entry; palate wound not looking so well; when the wound was dressed this morning a small piece of bone was removed, supposed to be from the horizontal plates of the two palate bones. To-day he complains of headache, so we may date his brain symptoms from this time, as they did not again leave him. Continue general treatment and apply ice-bag to occipital region; he has had quinia sulph. at various times for his septic fever, and symptoms have been met as they arose with appropriate treatment, *all* of which it is not considered necessary to fill this paper with.

December 30th. Little change in the patient's condition since the last entry; he seems to be growing weaker, there is more hebetude, palate wound looks unhealthy, with no tendency towards healing, the bone is denuded within reach of the probe; and attempts to examine the wound by means of reflected light by way of the mouth have failed, because the patient is too weak to stand enough manipulation for the purpose, and his mouth is partially closed in a tetanic manner. Diet: milk, milk-punch, and egg-nog. Morphia sulph. hypodermically, *pro re nata*, and quinia sulph. 0.30 ter in die. Cleansing the wound is now difficult, as he swallows all the liquids used, as well as his own foul discharges.

January 1st. Hebetude marked; right arm paralyzed; patient failing; he still takes plenty of nourishment and swallows freely; voice indistinct.

January 2. Losing power over the muscles of both sides; he cannot move arms or legs; has lost control of bladder and sphincter ani. He lies in bed perfectly helpless, but can be aroused and made to speak intelligently, but with difficulty; deglutition difficult. It is not easy to cleanse the wound, because he cannot spit at all and swallows the cleansing liquids and all they carry away with them. He still complains of headache. At a consultation to-day, between Dr. H. T. Percy and myself, the wound was probed for the bullets with a Nélaton porcelain-tipped probe, and though we thought we felt one we were not quite sure, and the mark of lead on the probe was not distinct. I now believed the balls to be in the body of the sphenoid bone, but this has since been found to have been a mistake, as

they were discovered after death in the basilar process of the occipital bone, at and *below* its junction with the sphenoid bone. Thinking that the lead was imbedded in necrosed walls of the sphenoidal cells we decided that we would not be justified in attempting to remove them from this dangerous site at this time, when nothing seemed likely to offer a chance of saving him, and any violence would probably kill him while he was undergoing the operation of removal. I wish to say, however, that of late years bullets remaining in the body have been regarded as too harmless altogether, and probing has been given too bad a name since counsel for murderers have learned to make the plea that probing kills their clients' victims, instead of the assassin's ball itself; a happy mean will probably correct both errors. While the patient under consideration was doing very well, we awaited some natural evidence of the location of the bullets as sloughing and exfoliation should proceed, hoping to remove them in good time, or to let them become encysted, and thus harmless. When the symptoms did come on, which showed that the lead was in a situation to do harm to vital parts, they appeared suddenly, and were of such a character that we became convinced no good could then be accomplished by trying to remove the foreign bodies from the neighborhood of important parts, with more or less violence. The diagnosis of meningitis from caries of the sella turcica, due to fracture of that portion of bone by the bullets, was made out at the consultation above mentioned, and then believed.

January 3. Patient sinking slowly; he lies in a comatose state, but can swallow food of a liquid character and stimulants. Respiration principally diaphragmatic, as the intercostal muscles are paralyzed to a great extent. Discharge from nose very slight.

January 4. Failing gradually, no other change to note.

January 5. He appeared to recognize Dr. H. T. Percy this morning when he addressed him decidedly, but lapsed into unconsciousness at once. Temperature 104° F., respirations 60 per minute, pulse 160 per minute; swallows with increasing difficulty.

January 6. Patient lies in a state of profound coma, respirations about 60, stertorous and growing shallow; temp. 102° F., pulse 160 to 180, and very weak. Fed by stimulating nutritious enemata, as he can no longer swallow. 9 o'clock P.M., failing rapidly, no pulse at wrist. Temp. 103° F.

January 7. Patient died at 2:05 o'clock A.M. Temp. at death 103° F. At 2 o'clock P.M. the autopsy was held by Dr. Percy, U. S. Navy, in the presence of Dr. J. Kerr, of this city, Drs. Woolverton and Nash, U. S. Navy, and myself. Eleven hours and fifty-five minutes after death, rigor mortis well established. Body much emaciated, marks of turpentine stupes on chest, they

having been used because of dyspnoea and signs of pulmonary affection; one mark of a small abscess on left arm from a hypodermatic injection.

In the centre of the roof of the mouth, extending antero-posteriorly, is an opening about $1\frac{1}{4}$ inch long by $\frac{3}{8}$ to $\frac{1}{2}$ inch wide, involving about $\frac{3}{4}$ inch of the bony palate and $\frac{1}{2}$ inch of the soft palate; about $\frac{1}{2}$ inch of the posterior portion of the septum narium is gone. The four upper incisors are gone, and the gum is found to be detached from their alveoli. On removal of the calvarium slight adhesions of the dura mater of the left side above the middle fossa were found; from this site pus flowed when the skull-cap was removed. When the brain was removed about $1\frac{1}{2}$ ozs. of clear fluid escaped from the spinal canal. Dura mater normal except over left middle fossa, where it was found congested, and had been detached from the bone at one portion by the burrowing of about $\frac{1}{2}$ oz. of pus, which had found its way from the basilar process and flowed to the left side across the middle fossa and to some distance up the left side of the parietal bone. The membrane over the basilar process was gangrenous; it had a bluish-black color, a foul odor, and was bulged out from its normal position.

The basilar process was found to be fractured and necrosed, and it crumbled under the knife like paper; it was dark-brown and had a very bad odor. On digging into it one ball was found, much flattened in shape, and just under it another, less disfigured. The third ball was almost of normal shape and was found a little lower down than the second one, and on the outside of the basilar process of the occipital bone, below its articular surface for the sphenoid bone. The odor in the vicinity of the inner surface of the basilar bone was that of caries, and the neighboring tissues were broken down and bathed in pus. The adjacent surfaces of the pons varolii and medulla oblongata, as well as their left sides, were covered with pus. The pia mater was intensely congested, but the brain tissue appeared to be normal on being sliced up. The ventricles had less fluid than is usually found in them. Death was due to exhaustion dependent upon general paralysis, which was caused by meningitis following necrosis of the basilar process from the gunshot wound.

The three bullets are herewith presented, as well as a cartridge such as he used, and it is still loaded; also an empty one, and the powder removed from it, 5 grs. in weight; also an unused bullet, which is $\frac{3}{8}$ inch in diameter and weighs 138 grs. avoirdupois. The three balls our patient used had a weight of 1 oz. avoirdupois in all. A service charge in one of these cartridges contains 72 grs. of powder and 138 grs. of lead; and a marine who fired one into his mouth during the last war "blew the whole top of his head off," in the words of my informant.

American Laryngological Association.

Eleventh Annual Congress, held in Washington, D. C., May 30, 31, and June 1, 1880.
(Concluded from page 851.)

SECOND DAY.—MORNING SESSION.

DR. T. AMORY DE BLOIS, of Boston read a paper describing

SOME OF THE MANIFESTATIONS OF SYPHILIS OF THE UPPER AIR PASSAGES,

and exhibited drawings showing the conditions which he had found.

DR. F. H. BOSWORTH, of New York, referred to the necrosis of bone which occurs in syphilitic ulcerations. He did not believe that syphilitic ulcerations extended from one part to an adjacent part. Such ulceration is due to the breaking down of a gummatous deposit, and does not extend beyond the limits of the original gummatous deposit. The necrosis of the bone he held to be due to the interference with nutrition of the bone caused by the original deposit, and that after the breaking down of the gummatous infiltration has taken place, the ulceration is kept up by the necrosed bone, and treatment should therefore be directed to this point. He agreed with the reader of the paper that potassium iodide was to be employed until the disappearance of the lesion, and that mercury should be used subsequently. Operative interference should be postponed until the syphilitic disease was well under control.

DR. C. C. RICE, of New York, said that in these cases there was often cicatrization and contraction above the visible adhesions, so that after the adhesions are freed, the results as regards phonation and respiration are not what would be expected. This contraction in the post nasal pharynx requires to be stretched in order to obtain good results. In regard to operations: in one case where there were adhesions, and where there had been no syphilitic manifestations for many years, he separated the adhesions with the galvano-cautery. The ulceration which followed took on an unfavorable character, and continued to spread despite constitutional and local treatment.

DR. J. N. MACKENZIE, of Baltimore, protested against the too vigorous removal of diseased bone from the nasal passages. It frequently happens that more is pulled out than is desired, and sometimes from dangerous regions.

DR. WM. H. DALY, of Pittsburgh, objected to the use of the galvano-cautery in tissues of the low vitality of syphilitic tissues. He believed that the galvano-cautery was a much-abused useful instrument. He felt satisfied that better results could be obtained in the fauces, in the nose, in the larynx, in any operation by using a sharp cutting instrument, and allowing as free hemorrhage as is consistent with good judgment. The freer the hemorrhage within certain limits, the

more certain is there to be immunity from septicæmia and rapid union.

DR. CHAS. H. KNIGHT, of Boston, read a paper entitled

NOTE ON THE GALVANO-CAUTERY IN THE TREATMENT OF HYPERTROPHIED TONSILS.

This paper was supplementary to one read two years ago. The galvano-cautery can not be satisfactorily used in young children, and in them the guillotine is preferable. In older children and adults the galvano-caustic point will prove of service. The galvano loop was especially considered. With this the operation can be done at one sitting. The portion removed by the loop does not indicate the real extent of the operation. A portion of the remaining tissue sloughs so that the operation with the loop was better than with cutting instruments. There seems to be very little more pain with the galvano-loop than with the guillotine. The former operation is, however, more disagreeable on account of the odor of burning flesh.

DR. T. A. DE BLOIS, of Boston, had used the electrolytic needle with good effect. Under cocaine, pain of the procedure is very slight. Half a dozen punctures each day will in a short time produce great diminution. This method is used only in adults. In children, the tonsils are very apt to diminish in size without treatment.

DR. C. E. SAJOURS, of Philadelphia, had frequently used the galvano point, but had to make as many as eighteen or twenty punctures in order to obtain satisfactory results. After the second visit the patient expresses very little objection to the operation. The galvano point is useful in the treatment of enlarged tonsils, especially where the density is not great. Here the cicatricial contraction assists in reducing the size.

DR. W. H. DALY, of Pittsburgh, believed that in the normal throat no portion of the tonsil extended beyond the line of the half arches, and in abscision of the tonsil our object should be to restore the throat as nearly as possible to its normal condition. This cannot be thoroughly done with the tonsilotome, but the operation must be completed with the forceps and bistoury.

DR. F. H. BOSWORTH, of New York, could see no reason for treating this condition by means of 18-20 punctures, when the whole trouble could be removed in a few seconds by a very simple operation.

DR. C. C. RICE, of New York, believed that there are few cases in adults where have been frequent attacks of tonsillitis, and the tonsils are greatly congested, where the galvano-cautery is of service.

DR. JOHN O. ROE, of Rochester, read a paper on
THE TREATMENT OF DISEASED TONSILS WHEN
UNATTENDED WITH HYPERTROPHY.

The conditions referred to are of marked clini-

cal importance, but their consideration is ignored by writers upon these subjects. The most common form of the disease of the tonsil is hypertrophy, and in children it is rare to find any other form. During adolescence the tonsils may diminish in size, but they do not return to their normal condition. The small tonsils in adults have often followed hypertrophy. This is a point in favor of the removal of enlarged tonsils. The two forms of disease of the tonsil to which attention was called, were, first, chronic disease of the crypts and lacunæ, and, second, fibroid degeneration of the stroma of the organ, the cicatricial form of the disease. The first is the result of chronic follicular catarrh of the tonsil, and is usually associated with chronic follicular catarrh of the pharynx. The treatment of these conditions is important, not only on account of the disease itself, but also because they are the source of recurrent trouble; and may cause reflex symptoms. Local applications are practically useless. The galvano-cautery, which is useful in the treatment of hypertrophied tonsil, may be employed here, but it is not as efficient as it is in the former condition. The treatment *par excellence* is ablation with the knife. The diseased crypts may be laid open and cauterized with chromic acid, or fused with nitrate of silver. Excision is, however, the best plan. It is rarely advisable to attempt removal of the whole mass at one time on account of the adhesions to the pillars. The use of cocaine lessens pain and hæmorrhage. In every instance in which the speaker had employed excision the cure had been perfect, with entire relief from the attendant symptoms.

DR. H. L. SWAIN, of New Haven, reported a case in which recurrent attacks of swelling of the lingual tonsil were caused by the presence of hard masses in the faucial tonsil. The attacks were subdued by treatment of the crypts, by cutting into them with the galvano-cautery, and thoroughly cauterizing their interior.

DR. J. SOLIS-COHEN, of Philadelphia, had seen many cases of spasmodic cough due to nothing but the presence of these masses in the crypts and lacunæ of the tonsil. These had been found not only in enlarged but also in apparently contracted tonsils. It is sometimes necessary to produce some gagging, so that the posterior portion of the tonsil presents, in order to discover this condition. In enlarged tonsil, the best treatment is probably excision, but in these atrophied tonsils he had pressed the matter out with a blunt scoop, and then applied a simple astringent, consisting of creosote gr. j, iodine gr. j, potassi iodide gr. v to glycerine 5j. If this does not answer, he cuts the crypt open with scissors, and scrapes them as thoroughly as possible. This affection is not as thoroughly appreciated by the profession as it should be. He had seen cases where cough existing for five, ten, or more years had been per-

manently relieved by treating this condition.

DR. WM. H. DALY, of Pittsburgh, referred to cases in which the patients were really sick, as the result of these lacunæ becoming filled with cheesy matter.

DR. F. I. KNIGHT, of Boston, described a case of long-continued irritative cough, in which the removal of a cretaceous mass as large as a pea from a crypt of the tonsil was followed by complete cure.

DR. SAMUEL JOHNSTON, of Baltimore, referred to three cases in which the collection, instead of consisting of soft, cheesy material, was hard, looking like spirales of bone, and adhered with great intensity. These bodies were not limited to the tonsil, but were also found on the lower part of the fauces and on the post pharyngeal wall.

DR. HARRISON ALLEN, of Philadelphia, stated that he had referred to this condition in a paper published in 1882. The solid matter is retained in the crypts. This pressure is often produced by the anterior fold. Sometimes the secretion has gotten out of the tonsil, but is still retained behind the fold. More frequently these masses are beneath the tonsil, under an adventitious membrane.

DR. J. SOLIS-COHEN, of Philadelphia, reported a case of

SARCOMA OF THE THYROID GLAND.

The case was one of sarcoma of the thyroid gland, with pressure on the right sympathetic nerve; unilatent tonic spasm of the laryngeal muscles; intermittent clonic spasm of the muscles of the opposite side: There was stenosis from the pressure of the tumor. For this tracheotomy was performed. This afforded relief for a number of months. Hæmorrhage occurred twenty months later, but was controlled without much difficulty. Gradually marked disturbance of the two pneumogastries supervened, and there was great interference with respiration. It was accidentally discovered that any irritation of the mucous membrane of the trachea would relieve the dyspnoea, and at once the lividity of the face would disappear. This effect was readily produced by touching the posterior wall of the trachea with a bent wire, passed through the tracheotomy tube. The patient died of exhaustion.

THIRD DAY—MORNING SESSION.

DR. C. C. RICE, of New York, read a paper on SOME UNUSUAL MANIFESTATIONS OF TUBERCULOSIS OF THE LARYNX.

The first unusual manifestation referred to was where syphilis and tuberculosis of the larynx co-exist. Here the lesions of one process mark those of the other. Here the prognosis depends upon which is the more active condition. This combination is more common than is generally supposed, and probably some cases of cure of sup-

posed tuberculosis should be placed under this head. A second unusual manifestation is the engrafting on the tuberculous process of a new tissue rendering the diagnosis difficult. This new tissue may be of two forms, either a granulation tissue, or a papillomatous growth. The third condition was adhesive inflammation at the anterior ends of the vocal bands. This must be rare, as the tubercular process shows little tendency to cicatrization and healing. It is liable to occur only when the cords are immovable, and there is general proliferation of tissue. The last condition referred to was one in which the tubercular deposit in one arytenoid was the only manifestation of the disease in the larynx, the remaining parts of the larynx being perfectly normal.

DR. WM. H. DALY, of Pittsburgh, was satisfied from his experience in three or four cases, that in some instances tubercular ulceration of the larynx may be cured. In these cases there was no evidence of syphilitic disease, and in at least some of them, the tubercle bacilli were found. Recovery has followed the use of alkaline sprays and inhalations, with the free use of iodoform. He believed that tuberculous ulceration of the larynx might occur without evidences of tubercular deposit elsewhere.

DR. J. C. MULHALL, of St. Louis, thought that there might be a catarrhal ulceration of the larynx, and that this was a curable condition. He did not think it would be easy to prove that tubercular disease of the larynx was ever primary, although it is sometimes the first sign of the condition. In tubercular ulceration of the larynx he had used pure lactic acid, and had seen the ulceration heal, but he could not say that he had ever seen life prolonged to any appreciable extent.

DR. F. I. KNIGHT, of Boston, had not the slightest doubt that tubercular ulceration of the larynx does get well. He had seen such ulcers heal under alkaline sprays and iodoform, and more especially under lactic acid. He thought that it was possible to have the tubercular disease of the larynx as a primary affection, but in the the majority of cases careful examination will reveal evidences of disease of the lung. He did not regard changes in the respiratory murmur and in respiration as the most important signs of early phthisis. He placed more reliance upon the localized râles which are heard on coughing. In order to develop this sign the patient should not inspire immediately before or after the cough, but should cough after a rest. He had seen but a few cases in which he regarded the disease as primary in the larynx.

DR. W. E. CASSELBERRY, of Chicago, reported a case in which he found catarrhal ulceration of the larynx. These readily healed under cleansing treatment, and there has been no return of the ulceration during a period of two years.

DR. J. N. MACKENZIE, of Baltimore, thought

that the question of the possibility of the existence of primary tubercular disease of the larynx had been settled by examinations upon the post-mortem table, where, in a few cases, careful examination of the body revealed tubercular deposit, nowhere but in the larynx. While a tubercular ulceration of the larynx may heal, this by no means indicates the cure of the disease. I have seen the co-existence of syphilis and tuberculosis in the larynx several times, and it is difficult to say which is the syphilitic and which is the tubercular ulceration. The only test is that of treatment. He had never seen what could be called catarrhal ulceration of the larynx. In regard to treatment he thought that more harm than good was produced by the employment of harsh measures. There is a form of ulceration which occurs in the later stages of phthisis, principally near the bifurcation of the trachea, which is probably due to the corrosive action of the sputa.

DR. W. C. GLASGOW, of St. Louis, believed that tubercular ulcers of the larynx were never healed. He had seen cases of ulceration of the larynx heal under treatment, but he did not consider these to be true tubercular ulcerations. These have healed under simple treatment. He had used with great satisfaction during the past two years the peroxide of hydrogen in the treatment of such ulcerations, and under its use there is rapid healing. He did not believe in primary tubercular disease of the larynx. In all the cases that he had seen, there had been more or less disease of the lungs. In true miliary tuberculosis of the larynx he had always found some evidence of disease in the lung, and these cases, he thought, never recovered. He had seen cases of catarrhal ulceration of the larynx.

DR. S. SOLIS-COHEN, of Philadelphia, read a paper on

THE OCCASIONAL TOPICAL USE OF SOLUTIONS OF NITRATE OF SILVER IN THE TREATMENT OF CHRONIC LARYNGITIS.

The cases reported were not due to nasal disease or obstruction; nor were they those in which all topical treatment is unnecessary. Where indigestion, constitutional disease or diathesis have been present, these have received due attention. It was simply of topical applications for the relief of local conditions that he spoke. All have encountered cases of chronic laryngitis, especially in singers, clergymen, lawyers, etc., in which, after all discoverable sources of irritation, local or general, have been removed and approved topical treatment, suited to the individual case, has been faithfully tried for a longer or shorter time, improvement takes place to a certain point and then stops. Perhaps all visible evidences of disease, except an irregular, pinkish striping of the vocal bands have disappeared, or perhaps there would be a faint uniform coloration or may

be only a loss of lustre; but something there would be that persisted and that prevented the patient from resuming with comfort full use of the voice in singing or speaking, or perhaps even in ordinary conversation.

It is in such conditions as these; the last obstinate remnants of the disease, that he had derived considerable satisfaction from the topical use, by sponge, cotton wool or brush, of weak solutions of silver nitrate, about 10 grs. to the ounce, applications being made every day for some two or three days, until some congestive reaction is produced; after that at longer intervals. In the course of treatment, too, in some cases, before reaching the last stage above described, I have found recovery apparently hastened by occasionally substituting stronger solutions of silver nitrate, 40 to 60 grs. to the ounce, for the iodized glycerine, tannin, tar or other routine application. A visible increase in congestion immediately follows the use of the silver solution, but this passes off quickly, and at the next visit great improvement is usually manifested. These applications are made once in about two or three weeks according to circumstances.

DR. C. E. BEAN, of St. Paul, described two cases of

*TUBERCULOSIS OF THE TONGUE,

one in a male and the other in a female. In both the disease had made extensive progress when they came under observation, and no operative measures seemed warrantable. In both there was well-marked involvement of the lungs. Death occurred in both cases a short time later. Attention was called to the differential diagnosis between tuberculosis, carcinoma and syphilis. Carcinoma is to be excluded by the absence of glandular enlargement and of the lancinating pains peculiar to that disease. The question of syphilis can only be determined by the history and by the effect of antisyphilitic remedies.

DR. J. C. MULLHALL, of St. Louis, read a paper on

THE LOCAL TREATMENT OF DIPHTHERIA.

The method of treatment which he suggested was based upon the following considerations: 1. That diphtheria is a germ disease. 2. That the specific microbe, in the majority of cases, selects the tonsils. 3. That unless checked by treatment, the colonization of these germs results in local putrefactive changes with subsequent involvement of the general system. 4. That implication of the larynx or of the nasal passages increases the mortality. 5. That the disease is acutely adynamic. It had occurred to him that in this disease it would be better to wash out the throat than to spray it. This is accomplished by means of an ordinary syringe, and in this way the throat can be washed out without difficulty. The patient should be kept in the recumbent position,

the head being brought to the edge of the bed. This procedure is repeated every hour during the day, and at no time is a longer period than three hours allowed to elapse. The only solution that he has used has been carbolic acid with compound solutions of iodine. The water is frequently saturated with boracic acid.

The post-nasal space requires careful attention. In every case of diphtheria the nasal cavities should be kept sterile from the first. Where it is certain that the nasal cavities are not affected, the insufflation of a non-irritating, antiseptic powder may be sufficient. Where there is uncertainty or where it is certain that infection has taken place, the nasal cavities are to be washed out with a weaker solution of the same kind, not more than a teaspoonful for each nostril. For this purpose he recommended a small glass syringe with a bulbous extremity to prevent injury to the nose. After cleansing he frequently resorts to solvents, and has obtained the best results with papoid. In laryngeal diphtheria, inhalation is the only practicable method. The inhalation of the vapor from slacking lime should not be forgotten. In several cases of laryngeal diphtheria he had obtained good results by placing the patient in a small room which had been fumigated with sulphur, and by keeping water to which has been added pine tar and turpentine constantly at the boiling point.

DR. W. C. GLASGOW, of St. Louis, believed that diphtheria is a blood disease rather than a local affection, and that the only objects in local treatment are cleanliness, disinfection and loosening of the membrane. One remedy he had used with advantage was the peroxide of hydrogen by spray. It seems to act by lifting up the membrane by the formation of gas. He considered the constitutional treatment as of the most importance, and he thought the bichloride of mercury and benzoate of soda were the most successful remedies. With these he uses very simple local treatment. In the cases of severe local manifestations the method described by Dr. Mulhall would be valuable.

DR. D. BRYSON DELAVAN, of New York, referred to the value of the bichloride and cyanide of mercury, which he had used for ten years in the treatment of diphtheria.

DR. W. H. DALEY, of Pittsburg, had on previous occasions recommended the use of calomel in the treatment of this affection, and he thought that it was as efficient as a local agent as it was active as a constitutional remedy. He believed that calomel in large and frequently repeated doses—2, 3, 4 or 5 grs. to children 1½ to 2 years of age—exerted a valuable therapeutic effect. He thought that a large part of the effect was from the local action upon the diphtheritic poison.

DR. HARRISON ALLEN, of Philadelphia, referred to the value of trypsin as a solvent for the diphtheritic membrane.

DR. F. WHITEHILL HINKEL, of Buffalo, read a paper on

SOME MANIFESTATIONS OF LITHÆMIA IN THE UPPER AIR PASSAGES.

The influence of lithæmia and allied conditions upon the upper air passages has received little attention in laryngology, as is shown by the scanty literature extant upon the subject. There is a distinction to be made between distinctly gouty sore throat and that due to lithæmia or some allied condition. The subjects of the latter may never have attacks of true gout, nor irregular manifestations of it—indeed, as a rule, they are not so affected. The term lithæmia is elastic in its application to cases varying from extreme digestive and nervous disturbance to almost normal health; consequently its manifestations in the upper air passages are not sharply distinguished, nor are they typical or pathognomonic. One of the most characteristic manifestations is a patchy or streaked irregular congestion of the mucous membrane of the larynx and pharynx. In the former case a dry explosive cough accompanies, in the latter uneasiness or positive pain is referred to the side of the throat, occasionally extending to the ears. These cases are notably irritated and made worse by stimulant applications. Local sedatives and general antilithic treatment give the best results. Occasionally acute naso-pharyngeal catarrh is a manifestation of an exacerbation of the lithæmic tendency. Alkaline and diluent medication with proper diet give more relief than local treatment. Obstinate relaxation of the nervous plexuses of the turbinated bodies in some individuals appears associated with lithæmia. Such cases stand operative—caustic—applications badly and receive little or no benefit from them. Some of these cases are much improved by antilithics and general hygiene. Others are intractable on account of uncontrollable lithæmic tendencies.

After electing the officers for the ensuing year (see p. 847) the Association adjourned to meet in Baltimore, the time of meeting to be determined by the Council.

DOMESTIC CORRESPONDENCE.

The Johnstown Disaster—An Appeal from Dr. Irving C. Blaisdell.

Dear Sir:—As a member of the Cambria Medical Society, as well as a member of the American Medical Association, I will report to you the loss of our Society so far as has been positively ascertained up to this date, although some other member may have already reported to you.

Dr. J. C. Wilson, of Conemaugh, an excellent Christian gentleman and for many years well-known in this county, was with his wife and

adopted daughter and one servant girl, with home and everything pertaining to it, swept away, nothing remaining to even mark the place of a once happy home. Next is Dr. G. C. Brinkey, of Johnstown, a very able and promising young doctor, a former secretary of Cambria Society. The third is Dr. M. W. Marbourg, of Johnstown, who had been in practice for many years, occupying the same office with his wife, Dr. Esther L. Marbourg, and who was well known in this section of country, and stood high as doctor, Christian and friend. His death was first reported to me by his wife, Dr. Esther Marbourg, on the Sunday following the flood. It was on the main street of Johnstown, but how different from its former self. The street was packed 30 feet high with every manner of débris, even to a steam engine that had been carried for miles as easily as though it was a block of wood. Cambria Medical Society was represented at the Chicago meeting by Dr. Esther Marbourg, and she is a member of the American Medical Association.

The doctors of Johnstown have lost heavily, not only in lives of friends, but property. One very worthy doctor and wife on the Sunday following the flood, while assisting in alleviating the wants and sufferings of others had nothing left for themselves except the clothing on their persons and a few dollars in the pocket of the doctor, which he generously divided with a brother doctor, left in the same condition, and who a few hours previous, had been counted wealthy, and so on. These are only two incidents among many that chanced to come under my notice.

I trust the loss and sufferings of the doctors of unhappy Johnstown will be brought before the Association when they shall have met in Newport. Very truly,

IRVING C. BLAISDELL, M.D.

Wilmore, Cambria Co., Pa., June 12, 1889.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Fifth Annual Meeting of the Fifth District Branch of the New York State Medical Association—The President, Prof. Wm. T. Lusk, delivers an admirable Address, in which he treats principally on the subject of Rupture of the Uterus and its Prevention and Treatment—Dr. T. M. Manley, of New York, on the Genesis of Tumors—Dr. F. E. Martindale, of Staten Island, reports a Case of Calcification of the Cardiac Left Ventricular Wall—Dr. T. H. Allen, of New York, on Traumatic Pelvic Cellulitis—Dr. J. G. Truax, of New York, on The Treatment of Acute Lobar Pneumonia—Discussion thereon by Drs. Alfred L. Carroll, E. R. Squibb, S. J. Murray and C. S. Wood.

The fifth annual meeting of the Fifth District Branch of the New York State Medical Association

tion, recently held in Brooklyn, was characterized by much good scientific work. In his opening address the President, Professor Wm. T. Lusk, congratulated the Branch on its prosperity, and expressed the opinion that the rapid growth in the membership of the Association, the zeal exhibited for the principles for which the organization stands, and the scientific merit of the work performed at these annual gatherings, were all prophetic of a long and useful life.

A considerable portion of the address was devoted to the subject of *Rupture of the Uterus and its Prevention and Treatment*, and coming, as they did, from so distinguished an obstetrical authority, his views were listened to with the deepest attention and interest. The case upon which his remarks were based was one in which the rupture was due to an undilatable condition of the cervix resulting from the presence of cicatricial tissue, and which had never been published. The patient, 33 years of age, was brought late at night to the Emergency Hospital, exhibiting signs of the most severe suffering. Her temperature was 99.5°, her pulse 140, and she was semi-maniacal. This, as far as could be learned, was her second pregnancy. Her first confinement had been a prolonged one, and had been terminated with instruments. The present labor had then lasted about thirty hours. Dr. Lusk was hastily summoned, and on his arrival he found that the membranes had long been ruptured. The uterus was firmly retracted upon the child, whose body was apparently situated in an oblique position with the head directed to the left, and rupture of the uterus seemed imminent. A digital examination showed that no dilatation of the cervix had taken place, and that this fact was due to firm cicatricial tissue situated at the internal os and extending somewhat over the uterine body. With the impending danger of rupture, he decided upon the Cæsarean section; but the woman's cries and importunities to desist at sight of the preparations for the operation led to hesitation, and this hesitation proved fatal.

While the question of operation was under debate she called for a chamber, saying that she wished to pass urine, and when placed upon the vessel began, in spite of every attempt to control her, to make violent straining efforts. Suddenly she fell back unconscious. The pulse was almost imperceptible, and the entire surface of the body became intensely pallid and covered with clammy perspiration. It was evident that uterine rupture had taken place; and the patient, who did not rally, died in about two hours. The autopsy was made by Dr. T. Mitchell Prudden, and he reported that the body of the child was found corresponding to the long axis of the mother's abdomen, with the back directed to the front and the head bent sharply in that direction. There was a considerable quantity of soft red blood-clot in the

abdominal cavity, and the rent in the uterus extended obliquely across the uterus from the upper portion to the right side of the fundus. The os internum was lacerated from the previous labor. The upper portion of the cervical canal was narrowed by dense cicatricial tissue, so that its diameter was about 2 centimetres, and the anatomical diagnosis therefore was: rupture of the uterus, with old, firm cicatricial contraction of the cervix uteri.

The case was rare, Dr. Lusk said, inasmuch as the cicatricial contractions were situated at the internal os and the lower uterine segment. Dilatation by incision or other artificial means was impossible. When cicatrices are limited to the lower part of the canal, as is ordinarily the case, the obstacle to the birth of the child is usually removed by the employment of the knife to sever the constricting bands. Again, the case furnished a new illustration of the fact that in spontaneous rupture the laceration is not of necessity confined to the thinned lower uterine segment, as has been maintained by some of the extreme partisans of Bandl's theory. He thought that the early employment of the Cæsarean section or the Porro operation would probably have saved the patient's life; although, at the late period of her admission to the hospital, either procedure would have partaken of the nature of a forlorn hope.

He then proceeded to briefly review the usual mechanism of uterine rupture and the means at our disposal for combating the mischief done. Spontaneous rupture during labor, he said, is not so rare an event that those engaged in busy practice can afford to be ignorant of the means of counteracting the tendency to a fatal result with all the resources of modern science. To Bandl belongs the merit of showing that nearly all ruptures begin in the lower uterine segment. In normal labors, during each pain the fundus and body of the uterus thicken, while the lower segment is stretched and thinned by the ovum or the presenting part of the fœtus. So long as no obstacle is met with which hinders the descent of the ovum or the fœtus this process ends in the conversion of the uterus and vagina into a continuous canal. Ordinarily, in advanced labor, the lower circumference of the body is distinguished from the stretched lower segment by a thickened ridge termed the contraction ring or ring of Bandl; though in easy labors this ring is often but slightly indicated.

When, however, the descent of the fœtus is hindered by any cause, the resistance of the ligaments which hold the uterus in position is overcome by the continued retraction of the fundus and body, and, as a consequence, the contraction ring is withdrawn upward, the lower segment is thinned and, in extreme cases, nearly the entire uterine contents may occupy the distended, passive inferior segment. Under these circumstances

the contraction ring is strongly marked, and may be felt through the abdominal walls above the pubis, or even in the neighborhood of the umbilicus. This movement upward of the contraction ring is limited somewhat by the pelvic and round ligaments and by the direction downward of the abdominal pressure; and, as these restraining agents operate more efficiently in first than in subsequent labors, it is not difficult to comprehend the relative frequency of rupture in women who have borne many children. As a result of the continued retraction of the body of the uterus, the lower segment may become so distended as to form little more than a membranous covering to the fetus, and the conditions favoring rupture are established. It has been maintained upon theoretical grounds that spontaneous rupture is arrested by the contraction ring, and this is certainly the rule when there has been no art intervention; but the case in question shows that the rule has its exceptions.

Undoubtedly the popularization of Bandl's teachings has contributed greatly toward the adoption of an intelligent prophylaxis in difficult labors. The situation of the contracting ring, which, when well defined, can usually be felt through the abdominal walls, furnishes in many cases an index of the degree of the threatened danger. The risks are further increased in cross births, in hydrocephalus of the child, and in lateral and anterior displacements of the uterus, owing to the augmented pressure exerted under such conditions upon a limited portion of the already over-distended tissues. If rupture occurs under these circumstances the accoucheur cannot wash his hands of responsibility. He ought to know that the faulty uterine positions should have been early corrected by judicious bandaging, the hydrocephalic head reduced by puncture, and that, in all forms of obstructed labor, there comes a time when patient waiting ceases to be a virtue and active intervention is demanded. The new learning teaches us that when the uterine efforts have proved unavailing to fix the presenting part, and the increasing distance of the contracting ring from the pelvic brim points surely to a dangerous thinning of the uterine muscle, the physician must promptly decide upon the indicated measures of relief. These, in head presentations, are version, craniotomy and the Cæsarean section. In neglected shoulder presentations only cautious attempts at version are justifiable, and the operator should never forget to support the head with one hand through the abdominal walls in such a way as to relieve the strain upon the over-distended tissues. In case of failure the persistent use of rude force is criminal.

Dr. Lusk stated that he dwelt upon these points for the reason that he did not believe that rupture of the uterus is by any means as rare as statistics would seem to indicate. While, however, insist-

ing upon a rule of personal accountability as regards the accoucheur, he said it was necessary to recognize that to Bandl's scheme there are exceptions. Now and then cases are reported in which primary rupture has occurred in the fundus and in the body, and where the lower segment has given way without antecedent signs or warnings. Having mentioned such a case in his own experience, he went on to say that rupture may be complete or incomplete. In the latter the tear is confined to the muscular structures, and the peritoneum remains intact. In most instances the hæmatoma resulting from the bleeding vessels dissects up the peritoneum for a certain distance beyond the tear. In the complete form the peritoneum likewise gives way, but to a less extent.

When the shock, the sudden stoppage of the uterine pains, the recession of the presenting part, the bloody discharge, the lateral tilting of the fundus, or its apparent disappearance in the case of the passage of the entire child into the abdominal cavity, have led to a diagnosis of rupture, the first indication for treatment is the speedy removal of the child. In selecting the manner for accomplishing this the important consideration to be kept in view is that it shall to the least possible extent increase the dimensions of the rent. In general terms he said it might be stated that with an undilated cervix, or in cases of extreme pelvic contraction, or after the passage of the head and arms through the rupture, and in all cases where the child passes entirely into the abdominal cavity, laparotomy is the more conservative measure. There is not only less shock, but the opening of the abdomen enables the operator to remove effused blood and amniotic fluid from the peritoneal cavity. Still, the not uncommon impression that the ruptured uterus furnishes a promising field for abdominal surgery does not take into account that, in many of the cases where laparotomy is clearly indicated, the patient is practically moribund.

The employment of the suture to close the uterine wound, in view of recent Cæsarean successes, seemed reasonable; but it was to be borne in mind that with ragged borders infiltrated with blood, with the peritoneum stripped off, and sometimes with air infiltrated into the subperitoneal connective tissue, the conditions for version are in no way comparable to those which exist in Cæsarean section. The Porro operation, he thought, promised better results, though the deep situation of the tear would make it difficult to secure a healthy pedicle. There should, however, be no hesitation about suturing the peritoneal surfaces; as the rupture is thus converted into an incomplete one, with its more favorable prognosis.

When the child could be removed by the natural passages without increasing the extent of the rupture, and when the latter was confined to the lower segment, he considered laparotomy of doubt-

ful value. In many such cases recovery, as far as life was concerned, had been secured by the employment of antiseptic irrigation and filling the gap with antiseptic gauze. At the same time drainage should be secured by means of iodoform wicking or the bent rubber tube; both drainage and packing being most effective when the tear is situated in the posterior wall. This plan of treatment is, of course, only useful where no infection of the abdominal cavity has taken place at the time of the rupture, and the best results are obtained, therefore, in cases of complete rupture. At the same time that drainage is used, compression of the fundus and body should be employed by means of the hands through the abdominal walls, and in case of hæmorrhage efficient aid can be furnished by pressure made upon the aorta. Finally, a carefully graduated compress should be placed around the uterus in order to maintain firm contractions. For this purpose he prefers the disc-shaped hydrostatic bag, partially filled with water; and in this condition and in all forms of post-partum hæmorrhage he has found it most effective.

Dr. Lusk also reported for the first time an interesting case of Cæsarean section, which unfortunately terminated fatally. The patient had a contracted pelvis and kyphosis, with an abscess from which there was a large accumulation of pus under the psoas muscle, and he expressed the opinion that if in this instance he had performed the Porro operation, and thus by removing the uterus relieved the pressure upon the intestines and other structures, the patient's life would have been saved.

The first regular paper was an elaborate one by Dr. T. M. Mauley, of New York, on *The Genesis of Tumors*; after which Dr. F. E. Martindale, of Staten Island, read the *Report of a Case of Calcification of the Cardiac left Ventricular Wall, following Subacute Vernicose Endocarditis*. The patient, a man 73 years of age, was suddenly attacked, April 13, 1886, with intense pain in the precordial region, accompanied by cold perspiration and dyspnœa, with a sense of impending dissolution. Dr. Martindale first saw him on April 15, when he made a diagnosis of subacute endocarditis, with circumscribed pericarditis at or near cardiac base. The etiology was obscure, as there was no history of either acute or chronic rheumatism, or nephritis, or of any exanthematous disease since childhood. From a careful inquiry into the previous history of the patient it was learned that in June, 1873, he had had a somewhat similar attack of cardiac trouble, though the exact nature of it could not be ascertained. He improved satisfactorily under treatment, but May 3d there occurred an embolic infarction of the right radial artery, and it was several months before the effects of this entirely passed away. Subsequently the patient had two attacks of marked dyspnœa, with pain in both legs and

œdema of the feet and ankles. By August 1st his general health and the distressing symptoms from which he had been suffering were greatly improved; but the auscultatory signs pointed to a chronic mitral insufficiency, and it was now clear that even should he survive for any length of time, he would labor under a permanent cardiac disability, with more or less remote compensatory hypertrophy and dilatation, and the functional disturbances resulting therefrom. In December œdema of the feet reappeared, and by the following July the œdema had extended to the middle of the thighs and implicated the scrotum and prepuce, while dyspnœa had again become so serious as to render the recumbent position impracticable. By the middle of September the anasarca had become general, and October 23d the patient died from œdema of the lungs.

At the autopsy the apex of the heart was found to be drawn backwards and firmly attached to the middle lobe of the left lung; the adhesions involving the two layers of pericardium and pleura. The left ventricular wall had undergone calcareous degeneration, and was very thin at this point. There was considerable hypertrophy and dilatation, but no valvular lesion was found, with the exception of a single tendinous spot on one of the mitral folds, if that could be regarded as such. The original diagnosis was at fault, therefore, only in attributing the apex murmur to a mitral stenosis, rather than to a roughened and unyielding endocardial surface.

In reviewing the history of this case, Dr. Martindale first put the inquiry, Was the initial attack in 1873 an endo- or pericarditis, and to what degree were either or both attacks concerned as factors in the subsequent calcification? Although the history did not make this apparent, he said, there must have been an etiological factor behind the first attack, since all authorities agree that primary idiopathic pericarditis is of extremely rare occurrence. In regard to primary endocarditis, also, there is absolutely nothing of a positive character known. We were therefore forced to the conclusion that the cardiac disability of 1873 must have had its origin in either a rheumatic or an exanthematous lesion at so early a period in the patient's life that it produced no permanent impression. There could be little doubt, he thought, that the first lesion, in 1873, was a circumscribed pericarditis, with a possible implication, to a limited extent, of the muscular tissue of the heart. Upon a careful examination of the specimen he said it could be seen that the endocardial surface of the calcified ventricular wall was smooth and polished, while the myocardium was the chief seat of the calcareous deposit; which further tended to substantiate the view that the disability of 1873 started as a pericarditis, but that the myo- and endocardium were not seriously implicated until the recurrence of 1886; for it

was hardly possible that the pathological conditions of the latter date could have existed thirteen years without any subjective symptoms.

For the embolic infarction of the radial artery he said there was needed no more reasonable hypothesis (assuming the myocardial lesion existing at this period to have been a sequence of the secondary pericarditis of 1873), than that the left ventricular pericardium was at this time attached by circumscribed adhesions to the left pleura; its contractile power being restricted not only by this, but by the gradual degeneration of the cardiac muscular tissue as well. The blood current through the left ventricle must have been churned, as it were, by the irregular and imperfect contraction of its normal muscular fibres upon the dense and non-contractile myocardial wall; and from this resulted, no doubt, the formation of a small coagulum and its subsequent location at the seat of radial infarction. As to the possible agency of sepsis in the causation of cardiac embolism, as illustrated in this case, Dr. Martindale, after referring to several modern authorities, stated his conviction that it was clear that nothing positive could be affirmed regarding sepsis as an etiological factor in the remarkable tissue metamorphosis observed in this specimen.

The last paper of the morning session was by Dr. T. H. Allen, of New York, on *Traumatic Pelvic Cellulitis*. This cellulitis, he said, was always associated with a unilateral or bilateral laceration of the neck of the uterus, and much more frequently with the former, because this was almost always deeper than the bilateral tear. He did not believe that in every case of laceration the involution of the uterus is arrested, but numerous examples of subinvolution associated with laceration had led him to consider the relation of cause and effect to be positive and direct.

Having reported in detail six cases in which he had performed the operation of trachelorrhaphy with very successful results, he went on to say that it should not be inferred from these that he was prone to operate in laceration complicated with cellulitis. This he would do only in exceptional instances. The opinion of the best gynecologists, he believed, was expressed in the following extract from a paper read by Dr. C. C. Lee, in 1881: "When any decided inflammation exists about the uterus, or so long as any tenderness can be detected in the neighboring connective tissue, it is unsafe to operate." Dr. Bache Emmet, in an article in "The American System of Gynecology," had, however, remarked: "In other cases the indurated and sensitive angle of laceration will be very marked and easily detected from the first, and in these cases there can be no question as to the necessity of removal of such a foreign body as a cicatrix." In this statement he thought Dr. Emmet had touched the keynote of the treatment; for he believed that this foreign body was the

cause of the coëxisting cellulitis. There was a limited class of cases in which the use of copious intra-vaginal injections of hot water and other well directed local as well as general treatment might improve, but not cure, a coëxisting cellulitis. This class of cases broadened the field for trachelorrhaphy, and to it Dr. Allen said he had given the designation "traumatic pelvic cellulitis," to distinguish it from the more diffuse form of pelvic inflammation. It was primarily caused by a wound—a tear—and nature in her unassisted efforts to repair the loss of continuity in the uterine neck built up a structure histologically different from the adjacent tissue, which operated in the same way as a foreign body. The operation of trachelorrhaphy removed the cicatricial tissue and completed the sphincteric arc of the circle with tissue identical in character; while it also had the effect of relieving, by the bleeding caused by it, the congested blood-vessels and lymphatics, and of imparting a new impulse to the process of nutrition. In concluding, Dr. Allen recapitulated his points in the following propositions:

1. Lacerations of the cervix uteri may result in the formation of cicatricial tissue, which produces chronic traumatic pelvic cellulitis.
2. In a limited number of these cases local or general treatment, or both, will not subdue this inflammation and pain.
3. Such treatment having failed, trachelorrhaphy may be performed successfully.
4. The dense mass of cicatricial tissue operates similarly to a foreign body, and its removal by Emmet's operation is a logical remedy which precludes the possibility of its reformation.

At the afternoon session Dr. J. A. Wyeth gave an analysis, with comments, of a number of important surgical cases recently treated by him. They comprised suprapubic lithotomy and other operations upon the bladder, ligation of arteries for various conditions, amputations, and resections of the knee-joint. In regard to suprapubic lithotomy, he said that after a career of varying fortune, in which it was at some times unduly lauded and at others entirely abandoned, he believed this operation had now attained a secure position which, on account of the improved facilities at the command of the modern surgeon, it would maintain permanently in the future. He also mentioned the various conditions in which it was applicable and in which it was, in his opinion, decidedly preferable to perineal section.

After some discussion of Dr. Wyeth's remarks Dr. J. G. Truax read a paper on *The Treatment of Acute Lobar Pneumonia* (see THE JOURNAL of June 29).

Dr. Alfred L. Carroll said that there could be no doubt that in many cases of pneumonia the need of arterial sedatives was manifestly indicated, and of all arterial sedatives venesection was the most powerful. There was, however, in addition

to the two classes of cases mentioned in the paper, a third class in which stimulus was urgently demanded on account of the feebleness of the patient; and which was well represented in the average seamstress of the city, for instance. In the second class mentioned by Dr. Truax there was danger of asphyxia; or, in other words, of the patient's drowning in his own fluid. In such cases he did not think any intelligent physician at the present day was afraid of drawing blood from the arm. The lungs were engorged with blood and the heart's action embarrassed, and venesection did not cure the pneumonia, but simply removed an obstruction. It was not, therefore, to be regarded as a curative; and in many instances other artificial sedatives were sufficient to secure the desired end. When these other sedatives failed it was unquestionably the physician's duty to resort to the lancet. The albuminuria spoken of by Dr. Truax as occurring in many severe cases of pneumonia was an indication of the venous congestion met with everywhere in the system.

Dr. E. R. Squibb inquired whether Dr. Truax had ever used *veratrum viride*, the old substitute for venesection, which often accomplished what venesection would in cases where the latter was inappropriate. He also asked whether Dr. Truax knew that he could get antifebrin (the use of which was advised in the paper) for half the money if he bought it under its other name of acetanilidine. The name antifebrin had been patented simply for the purpose of making money.

Dr. S. J. Murray said that by giving *veratrum viride* in doses of from $\frac{1}{2}$ drop to 2 drops every half hour he had never met with any difficulty in reducing the temperature. He was in the habit of carrying the drug to the extent of producing nausea; when he gave Dover's powder, and afterward stimulus, if it was required. Personally he much preferred *veratrum* to venesection, and he would certainly give it a trial in any case before he resorted to bleeding.

Dr. C. S. Wood said that in former years it was often noted that *veratrum viride* and antimony had a marked effect if they were administered after the patient had been bled, but did not exert their appropriate action if given before venesection. He was firmly convinced that, in the class of cases described by Dr. Truax, there was nothing that could compare in efficiency with bleeding.

In closing the discussion Dr. Truax said that he entirely agreed with Dr. Carroll that in feeble patients stimulants were demanded, and it was his practice to use them freely whenever they seemed indicated. In reply to Dr. Squibb he stated that he had often tried *veratrum viride*, but cases were sometimes met with in which neither it or any other agent would take the place of bleeding.

P. B. P.

The Best Climate for Consumptives.

Dear Sir:—It is with pleasure I have read the recent comments in THE JOURNAL, upon the best climate for consumptive patients, and thinking that perhaps the conclusions arrived at after spending nearly a year in this land of sunshine, may, in their humble way be of interest to some members of the Association, I send them to you.

Albuquerque is situated near the head of the fertile valley of the Rio Grande, is nearly five thousand feet above sea level, surrounded by mountains and highlands, which act as barriers against cold winds and blizzards. The soil is a sandy loam, the water pure and good. There being no station of the signal service here, I am unable to obtain a correct record of the temperature. The nearest station is at Santa Fé, two thousand feet higher, and sixty miles farther north. A fair comparison cannot be made. The winter temperature at Santa Fé and Las Vegas is considerable colder than at this point. Imagine the seasons as you have them in Illinois with the months from November 1 to the last of March taken out, and those remaining extended to fill the gap, with no oppressive heat and hot nights, little rain except in August and September, very few cloudy days, a bracing balmy atmosphere, and you have an Albuquerque climate. Twice during the winter the thermometer registered at zero; only three times has snow fallen in the valley, to melt and disappear in a few hours, except once when it remained a day or two in shady places.

The whole winter with these exceptions, has been like one long eastern October, with just enough frost during the night for a tonic. At this altitude the air is pure and stimulating, free from poisonous germs. There is an abundance of good sunshine, and the cool mountains in which to spend a delightful summer reached by a beautiful drive of twelve miles on the mesa.

The improvement in health of many has been almost miraculous. Those narrow chested individuals with a general debilitated appearance, rarely fail to have their chests expand and become strong and robust, at this altitude. Those who come here, in the first stages of consumption, with but a slight softening of the lung tissue will in all likelihood be cured. Those patients with small cavities in their lungs may be sure of being greatly benefited. Where there is extensive tubercular deposit with a large amount of broken down tissue, length of days may be added to their lives; some seem to regain their strength and live for years.

Those patients with a hæmorrhagic tendency, and those in the last stages of consumption ought not to come into these high altitudes too suddenly; they should be sent around by way of El Paso, Texas; slowly working their way up the valley,

until they have reached a locality, where improved health is assured. Patients who come here for their health must come with the expectation of staying four or five years, if not the remainder of their lives. Many that come, are to all appearance cured or greatly benefited, then go back to their old homes in the east, only to have a relapse, returning to Albuquerque when it is too late.

Climate will not do every thing. Too often those who go away from home in search of health, violate all hygienic rules. I have seen invalids, in the name of exercise do that which would make a strong man weary. I have known young men, in the last stages of consumption, spending their time in "riotous living," after leaving home and dear ones, in search of a new lease of life. The physician's duty does not cease with simply advising their patients to make a change in climate. Lay down rules for them to follow, instructing them to take a moderate amount of outdoor exercise, spending as much of their time in the open air as is consistent, enjoying their winter evenings indoors, at some pleasing occupation or amusements that are not debilitating; tell them to forget self; impress upon them that "care to our coffin adds a nail no doubt, and every grin so merry draws one out."

I am often asked: "What effect does the New Mexico climate have upon rheumatic and other diseases?" The larger proportion who come to this region suffering from rheumatism find a complete cure; a few obtain no relief. My theory now is that those who come from the States along the Great lakes, where the air is laden with moisture, will be greatly benefited by a sojourn here, but those from Kansas, Nebraska and States of a dryer clime will not receive the good expected. My opinion may change with time. Many dyspeptics are cured by coming here. Those who are suffering from the moist form of catarrh find great relief. Cancerous troubles are almost unknown.

CHARLES E. WINSLOW, M.D.

Albuquerque, N. M., May 11, 1889.

NECROLOGY.

Dr. Daniel W. Hand.

Dr. Daniel W. Hand, of St. Paul, Minn., died in that city June 1, in his 55th year, of uræmia. Dr. Hand was born at Cape May Court House on the 18th day of August, 1834. He was a graduate of the University at Lewisburg, Pa., and subsequently graduated in medicine at the University of Pennsylvania with high honors. Dr. Hand went to St. Paul in March, 1857, where he practiced his profession until July, 1861, when he volunteered his services and was appointed assist-

ant surgeon to the 1st Minnesota Regiment; he was afterwards, by examination, appointed Brigade surgeon. At Fair Oaks his horse was shot from under him, and he himself was wounded. May 18, 1863, he was captured and lodged in Libby Prison, was, however, soon exchanged and transferred to Newbern, North Carolina, and for two years from August 11, had charge of the medical department of the State. While medical director he rendered important services during a serious small-pox epidemic, which his quick action and stringent hygienic measures effectually checked.

In the month of September, 1864, yellow fever broke out at Newbern; between September 6, and November 1, over 1,200 citizens perished, including eleven of the assistant surgeons. Dr. Hand alone escaped until the epidemic had almost subsided, when he also was stricken down. His recovery was rather a rapid one, but unfortunately left him with the kidney trouble which was the final cause of his death.

In 1865 he was mustered out of service with the rank of Colonel. He soon returned to St. Paul, where he practiced medicine until his death. His death will be lamented by a large circle of friends and patients. The profession loses in him one of its most prominent members. He was always at the head of any undertaking to better the standing of the profession in his State, was for a long time a member of the State Examining Board, for many years President of the State Board of Health, he had the welfare of the people always at heart. He was a member of the American Medical Association. His many kindnesses to the younger members of the profession, his uniform cordiality to the older, and his professional ability, made him the foremost of the consultants of the State.

Scientific, conscientious, affable, energetic, he was an ideal physician honored and beloved by all.

Dr. Ellen A. Ingersoll.

Ellen A. Ingersoll, M.D., was born in Canton, Ill., April 24, 1844. She attended school in her native city until 1865, when she entered Dio Lewis' school at Lexington, Mass., where her interest in the science of medicine was awakened. Her medical studies were begun in 1872 with the late Dr. G. W. Wright, of Canton, and took her first course of lectures at Keokuk, Ia. She entered the Woman's College at Philadelphia, and graduated March 13, 1874, after which several months were spent in the Woman's Hospital of Philadelphia and in the New England Hospital of Boston as resident physician. She returned to her native city fully equipped for practice, and gained the confidence and respect of her colleagues, as well as that of the community at large.

She never failed to respond to the call of suffering and gave freely of her highest powers in administering to the poor. She became a member of the Illinois State Medical Society in May, 1875, and of the American Medical Association three years later, and was appointed several times to represent the State Society in the annual meetings of the Association, and was a delegate elect to the convention of that body this year, 1889. Some papers of great merit were read by her before the Society, and one year she acceptably filled the chair of Vice-President. On Thanksgiving Day, November 29, 1888, she died from heart failure after a surgical operation.

By the death of Dr. Ellen A. Ingersoll the Illinois State Medical Society and the medical profession have been deprived of a most valued member, one whose devotion to its principles and practice was characterized by the highest regard for professional honor. The medical women have lost one of the most noble and gifted of the sisterhood.

BOOK REVIEWS.

DISEASES AND INJURIES OF THE EAR. By CHARLES H. BURNETT, A.M., M.D. Philadelphia: J. B. Lippincott & Co. 1889.

This little book of 154 pages is one of a series known as "Practical Lessons in Nursing." It is free from technical terms, and written so as to be perfectly intelligible to the non-professional; containing clear descriptions of the various affections of the ear; their causes, and relations to other diseases, so that they may, if possible, be avoided; but if contracted, their early recognition will prevent experimental and erroneous forms of treatment. Therapeutically its aim has been to show the inexpert what to avoid in the treatment of ear diseases, rather than what they may try to do for their relief. In speaking of diseases of the middle ear, the author has a few good words in regard to the use or rather the abuse of quinine, which is often taken in large doses to abort a "cold in the head." Nothing in fact is more likely to bring on a disease of the ear, which might otherwise escape than large doses of quinine. It causes congestion of the mucous membrane of the middle ear at a time when the predisposition to inflammation in that locality is intensified by the condition already existing. Those portions of work devoted to hygienic management are good.

MISCELLANY.

THE NEWPORT MEETING ENTERTAINMENTS.—Delegates are reminded that the ladies accompanying them

are invited to all the entertainments provided. The afternoon entertainments are intended more especially for the ladies, and those delegates who are chiefly seeking mental rest.

Tuesday Afternoon, June 25.—Excursion to U. S. Torpedo Station, Goat Island. By invitation of the commanding officer, Captain C. F. Goodrich, U. S. N. A practical demonstration of the explosion of torpedoes will be given at 4:30 P.M. Lt. J. C. Wise, Surgeon U. S. N., of the Committee of Arrangements, and Medical Officer of the Station, will introduce the visitors. Government steam launches will leave the ferry wharf at 4 P.M., and every few minutes thereafter.

Tuesday Evening, June 25.—Reception at Music Hall, and Celebration of the 250th Anniversary of the Foundation of Newport, under medical auspices, 8:30 to 11 P.M. Dr. Francis H. Rankin, President of the Newport Medical Society, and Secretary of the Newport Board of Health, will preside. Addresses of welcome will be given by Hon. Thomas Coggeshall, Mayor of Newport, on behalf of the citizens; and Dr. Henry E. Turner, President of the State Board of Health, and Ex-President of the Rhode Island Medical Society, on behalf of the Newport profession. (A brief address had been promised by Hon. Francis Brinley, President of the Newport Sanitary Association, but upon June 14, at the venerable age of 89, he has deceased.) An oration will be delivered upon John Clarke (1609-76), the physician, clergyman and statesman, who procured the charter for Rhode Island from Charles II, in 1663, and who has been immortalized as "The Founder of the Civil Polity of Rhode Island," upon the marble slab erected by the Newport Medical Society, at the Historical Society's Hall, by Hon. William P. Sheffield, late of the U. S. Senate. There will be music by the celebrated Fort Adams band, kindly offered by the commanding officer of the Fort. After the addresses the seats will be cleared away, and an informal reception will be held.

Wednesday Afternoon, June 26.—Excursion to U. S. Naval Training School, Coaster's Island. By invitation of Commander F. J. Higginson, U. S. N., in command of the station, a battalion drill of the boys of the school will be given at 5 P.M., and opportunity to inspect the U. S. training ship "New Hampshire." Lieut. J. L. Neilson, Surgeon U. S. N., of the Committee of Arrangements and medical officer of the station, will introduce the visitors. Government steam launches will leave Commercial wharf, north side, at 4 and 4:30 P.M. Those who prefer, can reach the island by carriages, via the causeway at end of Third St.

Wednesday Evening, June 26.—Vocal and instrumental concert at the Opera House, at 8 P.M., under the direction of Dr. T. A. Kenefick, chairman of the Sub Committee of Entertainments.

Thursday Afternoon, June 27.—Excursion to Fort Adams. By invitation of the commanding officer, Col. John Mendenhall, U. S. A., there will be a light battery drill at 5:30 P.M. Major S. M. Horton, U. S. N., Post Surgeon and of the Committee of Arrangements, will introduce the visitors. Government steam launches will leave Ferry Wharf at 4:30 and 5 P.M. The fort can be reached, if preferred, by carriage.

Thursday Evening, June 27.—Promenade concert, and reception by the Newport profession, at the Ocean House at 8 P.M. Music by the band of U. S. ship "New Hampshire," kindly offered by Commander Higginson, U. S. N., for the occasion.

Friday Afternoon and Evening, June 28.—Excursion upon Narragansett Bay, and clam-bake, at the invitation of the Rhode Island Medical Society. Dr. John W. Mitchell, of Providence, President of the State Society, will receive in behalf of the hosts of the festival, and will bid God-speed to the parting guests.

LAKE COUNTY (ILL.) MEDICAL SOCIETY.—The Sixth Annual Meeting of the Lake County Medical Society was

held Thursday, June 6th, in the Waukegan Court House, the profession of the county being well represented. Dr. Tombaugh, the retiring President, gave an interesting address upon "The Use of Opium in Labor," which was followed by a general discussion. Dr. Carter reported as delegate to the Illinois State Medical Society. The following officers were chosen for the ensuing year: President, Dr. Wm. Sweetland, Highland Park; Vice-President, Dr. F. C. Knight, Libertyville; Secretary, Dr. A. C. Haven, Lake Forest; Treasurer, Dr. Beatrice Pearce, Waukegan. Drs. Beatrice Pearce, Marie F. Barry, J. M. G. Carter and F. C. Knights were chosen to read papers at the next session of the Society, the first Thursday in September.

OBITUARY.—Dr. James Ethelbert Morgan died recently at his residence in Washington, D. C., aged 64 years. Dr. Morgan was a native of St. Mary's County, of the old Maryland family of that name, and was a graduate of Saugston College. Dr. Morgan, shortly after his graduation over forty years ago, settled in South Washington, when that portion of the city was but a few hamlets united only by pathways across the commons, and it may be said he grew up with that section. He represented the old Seventh Ward several years in the Council and served a number of terms on the Board of School Trustees, and was for some time an active member of the old Board of Health. In his office he had as students Dr. C. V. Boorman, Ham, Leech, S. P. Fenwick and others, who succeeded to his South Washington practice when he moved to his late residence on E street, some ten or twelve years since. He also has three sons in the profession.

Dr. Morgan made no pretensions to that kind of charity which is seen of men, but the recipients and his intimate friends know that quietly he did a great deal to relieve suffering outside of his medical duties. Like Dr. Borrows, the deceased took much interest in local military affairs. The doctor was greatly loved, and his death is universally regretted.

DANGERS FROM CONSUMPTIVE FELLOW-TRAVELERS.—In the *Illustrated Med. News*, March, 1889, p. 294, attention is drawn to the danger run from traveling with consumptive patients. There is strong evidence that on board ship it is very easy for husband and wife to communicate the disease to one another. It is even possible for a healthy person to become consumptive if sharing the same cabin as anyone known to have the disease. On board ship there is often a great deficiency of fresh air, and the cabins are badly ventilated, to say nothing of the danger of taking the poison from the upsetting of utensils which contain sputum. The danger of traveling with infected fellow-passengers in a railway carriage or public conveyance may be so infinitesimal as practically to be neglected, yet when one is brought into contact with an infected individual for a considerable length of time, and more especially when the air which the infected and non-infected individuals are forced to breathe is neither large in quantity nor good in quality, the danger is undoubtedly a real one, and it is to be hoped that means will be taken to prevent the spread of so fatal a disease in this manner.

LETTERS RECEIVED.

Goode, Buffalo Lithia Springs, Va.; S. S. White Dental Mfg. Co., Philadelphia; Dr. Thos. H. Manley, New York.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from June 8, 1889, to June 14, 1889.

By direction of the acting Secretary of War, First Lieut. Philip G. Wales, Asst. Surgeon (recently appointed), will proceed from this city to the Presidio of San Francisco, Cal., and report for duty to the commanding officer of that post, reporting also by letter to the commanding General, Division of the Pacific and Dept. of California. Par. 3, S. O. 132, A. G. O., June 8, 1889.
Capt. Charles M. Gandy, Asst. Surgeon, upon the abandonment of the post of Ft. Concho, Texas, will report in person to the commanding officer, Ft. Clark, Texas, for duty at that station, to relieve First Lieut. Ogden Rafferty, Asst. Surgeon, reporting also by letter to the commanding General Dept. of Texas.
Lieut. Rafferty, on being relieved by Capt. Gandy, will report for duty to the commanding officer, San Antonio, Texas, reporting also by letter to the commanding General Dept. of Texas. Par. 7, S. O. 133, A. G. O., Washington, June 10, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending June 15, 1889.

Asst. Surgeon O. D. Norton, ordered to the Naval Hospital, Chelsea, Mass.
P. A. Surgeon J. H. Hall, detached from the Naval Hospital, Washington, D. C., and granted six months' leave to go abroad.
P. A. Surgeon D. O. Lewis, detached from the Naval Academy and to Hospital, Washington, D. C.
Surgeon Geo. A. Bright, detached from the Navy Yard, Norfolk, Va., and wait orders.
Surgeon R. A. Marmion, detached from the receiving ship "Franklin" and to Navy Yard, Norfolk.
Surgeon D. N. Bertolette, ordered to the receiving ship "Franklin."
Medical Inspector B. H. Kidder, ordered to the Naval Academy, Annapolis, Md.
Medical Inspector T. C. Walton, detached from the Naval Academy and to the U. S. S. "Chicago."
P. A. Surgeon H. G. Beyer, ordered to the training ship "Portsmouth."

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending June 8, 1889.

P. A. Surgeon F. W. Mead, ordered to examination for promotion. May 31, 1889.
P. A. Surgeon P. M. Carrington, to proceed to Johnstown, Pa., on special duty. June 3, 1889.
P. A. Surgeon W. P. McIntosh, when relieved at New Orleans, La., to proceed to San Francisco, Cal., for temporary duty. May 29, 1889.
Asst. Surgeon A. C. Smith, relieved from duty at Louisville, Ky.; ordered to Marine Hospital, New Orleans, La. May 29, 1889.

SURGICAL REPORTS.

Read before the Chicago Medical Society, May 7, 1889.

BY CHRISTIAN FENGER, M.D.,
OF CHICAGO.

It is hardly proper to call this a paper, as it is simply the presentation of specimens, with a few remarks.

I. RUPTURE OF THE KIDNEY.

I will commence with the case of rupture of the kidney, which was as follows: Otto Lehmann, 20 years old, from Rockford, Ill., came into my hands February 3, 1888, and gave the following history: He had always been strong and healthy until about a year ago, when the following accident occurred: While walking along a wooden sidewalk built about 5 feet above the ground, he stepped over the side and fell to the ground. He experienced the most violent pain in the right lumbar region, had to be carried home, and any attempt to move him aggravated the pain. There was some blood in the urine for perhaps a week, after that time the urine became normal; nevertheless he lost greatly in flesh and strength, the pain in the right side remained and a swelling formed. When I saw him, a year after the injury, he was pale, somewhat emaciated, and in the right side there was a fluctuating swelling reaching from the ribs to the pelvis and to the median line. His temperature was 101° , showing some fever all the time. An exploratory puncture showed this swelling to contain urine, which was slightly turbulent and contained a few pus corpuscles. The operation was lumbar incision and drainage, 1 quart of fluid was evacuated from the swelling. But the fever remained and after several weeks even increased, the temperature varying from 101° to 103° , with profuse sweats and progressive emaciation. I concluded then that suppuration or sepsis was going on, that the most natural location of that sepsis was the tissue of the kidney, and I resolved on extirpation.

I extirpated the kidney on April 12 by the usual lumbar method and T-shaped incision. At that time there was found, besides the kidney, which is here presented, a large abscess cavity ex-

tending up towards the diaphragm and down in the large pelvis. After the operation the condition of the patient was not improved, he gradually got worse and finally exhibited symptoms of inflammation in the corresponding lung, from which blood and pus was expectorated, and he died May 3, three weeks after the extirpation.

The kidney, which was removed one year after the original injury, presents the following appearance: It is divided into two portions, an upper and larger, and a lower and smaller one, with a transverse place of division in which there is an opening through, which leads into the portion of the pelvis belonging to the lower portion of the kidney; otherwise the tissue of the kidney is normal. When the pelvis was opened it was found that the lower portion of the kidney was excluded from the pelvis by the transverse mass of cicatricial tissue seen in the specimen. I therefore think it likely that the urine contained in this space was from the lower portion.

The autopsy showed an abscess cavity in a portion of the kidney, extending to the lower surface of the liver, in the right lobe of which was an abscess the size of a hen's egg, communicating with a subdiaphragmatic collection of pus between the convexity of the right lobe and the diaphragm. From the latter abscess cavity a communication existed through an opening in the diaphragm, up into the pleural cavity, in the lower half of which was an empyema which had perforated into the lung tissue, and emptied into a large bronchus of the lower lobe.

I wish to make a few remarks on the class of cases to which this specimen belongs, namely: subcutaneous ruptures or injuries to the kidney.

One hundred and eight cases of subcutaneous injury to the kidney have been collected lately by Grawitz.¹ Of these 108 cases we can judge of the severity of the lesion by the fact that fifty died. As to the etiology, we can distinguish between direct and indirect injury to the kidney. The direct injury is by a blow, by a foreign body, falling against a sharp edge, as a rail on a railroad track, being driven over by a wagon wheel, the kick of a horse, a heavy body falling against the side of the patient, etc. The direction of the body

¹Langenbeck's Archiv. für Klinische Chirurgie, Band xxxi, p. 419.

that causes the injury is not necessarily directly over the kidney; it may strike the anterior surface of the abdomen or either loin, as well as the side. Indirect injuries, which are also known as ruptures, may be an injury to the whole body, for instance a man falling from a great height or from a horse to the level of the ground, not striking against any portion of the body in particular. This was true in this case, where the boy fell 5 feet down on the level ground. Also when a laboring man digging a well is buried by the caving in of the earth, the same thing is shown. Such injuries, acting diffusely on the abdomen, do not cause local symptoms, ecchymoses, abrasions, etc., but sometimes fractures of the lower ribs or of the spinous processes of the vertebrae point to a severe injury.

As to frequency, Grawitz remarks that it is probable that subcutaneous injuries to the kidneys are more common than is usually believed, and much more common than these 108 cases would imply, inasmuch as there undoubtedly are a number of cases where the hæmaturia is slight, passing off in a week, and so they are not recognized or published.

As to the anatomy, direct violence can of course crush the kidney tissue; a slight injury may cause a rupture which is limited to the tissue of the kidney without opening either into the pelvis or capsule, or it may open into the pelvis and capsule, or may rupture also the peritoneal covering of the kidney, or finally, the whole kidney may be crushed. The slighter injuries almost always present themselves, as in this case, as ruptures, and the direction of the rupture is almost always the same as in this case, transverse, so that the kidney is divided into an upper and lower portion transversely, whatever the direction of the body causing the injury may have been. This has its explanation, says Grawitz, probably in the fact, first, in the foetal shape of the kidney, consisting of numerous small lobuli, twelve to fifteen in number, *renculi*, as they are called, divided from one another by transverse sulci. It has been shown by Hatayama, in experiments on animals with transverse lobulation of the kidneys, that when a rupture is produced it is a transverse rupture. Attempts to determine this by Grawitz and Caspar Leman, by rupturing the kidney on dead bodies, have not been successful; it seems as though life is necessary to produce rupture of the kidney in that way. The natural consequence of rupture of the tissue is hæmorrhage, and the quantity of blood is of course variable according to the extent of the injury. The larger the vessel the more the extravasation.

The following points should be taken into consideration as to the danger of immediate hæmorrhage: If the capsule is not ruptured, then the blood will dissect away the tissue of the kidney from the inner surface of the capsule and there

will come a time when the tension here becomes extensive enough to stop the hæmorrhage mechanically. If the capsule is ruptured, extensive extravasation in the pararenal tissue may take place and form a hæmatoma that may extend from the diaphragm to the pelvis, but even here there will finally be some tension which will tend to stop further extravasation. When the peritoneum is ruptured over the kidney then the blood has access to the peritoneal cavity, and of course there is no tension that will have a tendency to stop the hæmorrhage, consequently these are the cases in which there is most danger of acute fatal hæmorrhage. In children, rupture of the peritoneum is more common than in older people, partly because the peritoneum is thinner and partly because it is more tense over the surface of the kidney. If the pelvis of the kidney is ruptured then the blood goes down the renal passages and appears in the urine, except where there is a simultaneous rupture of the ureter.

As to the symptoms: pain is almost always present, and this pain is usually so violent that patients are unable to walk or stand. Shock is not particularly characteristic for injury to the kidney, but, when connected with anæmia and followed by collapse, points to severe intraperitoneal hæmorrhage. A tumor is felt only in case of rupture of the capsule and extrusion into the perirenal tissue. Hæmaturia is almost constantly present, rarely entirely absent, but often of short duration only. It is slight in small ruptures, copious in rupture of large vessels of the pelvis, and sometimes intermittent when a coagulum temporarily stops up the ureter. It may be intermittent when the thrombosis that is primarily found in the vessel later disappears, for instance, if it is being washed away with urine; the result of coagulation on its passage down may be renal or vesical colic. The hæmaturia usually lasts from one to two weeks, it is very seldom that it stays as long as the fourth week.

As to the course and termination, the following is known: Fifty-eight cases out of 108 recovered. The course is usually divided into two stages, a non-suppurative primary, and a suppurative secondary stage. It is an error to divide the course of such an injury in this way, inasmuch as a given case does not necessarily pass from one into another; consequently it would be as well to divide them into cases where we have healing by first intention on the one side, and healing by second intention and suppuration on the other side (Grawitz); or to divide them into aseptic and septic cases. Aseptic healing took place in forty-six out of fifty-eight recoveries (Grawitz). In the milder cases the blood disappears, pain ceases and recovery takes place in one to three weeks. In severe cases it took one to three months. Experiments made by Maas on animals to determine the effects of crushing and rupture of the tissues

of the kidney show that aseptic healing is the rule, even when there is extensive crushing of a large portion or all of the kidney, by aseptic atrophy with absorption of the dead tissues and replacement with connective tissue, and compensating subsequent hypertrophy of the other kidney. This takes place in from eight to thirty days, usually. Suppuration took place in seventeen out of the 108 cases, or in ten of the recoveries. The cause of the suppuration of course need not be discussed; it is microbes, pus microbes perhaps, but microbes. This was suspected as far back as in 1869, when Billroth's assistant Menzel, and Simon mentioned it, showing for the first time that healthy urine does not produce suppuration but that decomposing urine does; but they left it uncertain whether it was the ammonia in the decomposed urine or the microbes, which Billroth had then paid considerable attention to, which caused the suppuration. Tillmans states that extensive crushing of the area of the kidney tissue, when no suppuration takes place, causes only a limited parenchymatous inflammation around the dead tissue. Aseptic silk sutures through the kidney tissue do not cause suppuration, but will heal just as well as in any other tissue. A diffuse parenchymatous nephritis from traumatism is rare and has been described in only three cases.

The sources of infection are the blood, the urinary passages and, finally, the abdominal organs. The blood is very rarely a source of secondary infection to crushed tissues mixed with urine. Rinne has shown that putting woolen threads through the kidney tissue, although they cause more mechanical injury than do silk or linen, will heal antiseptically even when pus microbes have been injected into blood-vessels or into the peritoneal cavity before, at the time, or after the threads have been put in, which speaks very strongly for the blood being only occasionally the carrier of the microbes to infect the crushed tissue. The urinary passages, then, are the ones to look to, and of course any previous condition in the shape of gonorrhœa or cystitis, or (what from the history of the numerous cases seems to be well proven, in some of them at least) from catheterization with an unclean catheter after a rupture which has caused coagulation of blood in the bladder, has caused the infection of the injured portion of the kidney. The course of the suppuration is the following: either a perirenal abscess or, what is more grave, suppurative nephritis; multiple abscesses in the kidney tissue, either acute or chronic, the acute being by far the most common.

Death took place in fifty cases out of the 108, a mortality of 46 per cent.; but of these cases there were a number with complicated injuries of the abdominal and thoracic organs, which ought to be excluded from subcutaneous injuries to the kidney; when these have been excluded there remains a mortality of 35 per cent. (Grawitz). The

most common cause of death is immediate hæmorrhage, the patient dies within a couple of hours or within the first day or two; that is, when the pelvis is opened and the large vessels of the kidney ruptured. The rupture of the peritoneum does harm mostly by not giving resistance enough in helping to check the hæmorrhage, inasmuch as blood and urine when aseptic, even in considerable quantities, are, as has been shown by Wagner, readily absorbed from the abdominal cavity. Later continuous hæmorrhage that comes on in the two or three following weeks takes the life of some patients, but only half as many as the primary hæmorrhage (in eight of Grawitz's cases). Then comes the suppuration or sepsis, which is, as has been seen, in the minority; suppurative nephritis, paranephritic abscess, peritonitis, pleuritis by extension of the abscess, or metastatic. Finally, suppression of the urine rarely causes death (in three only of Grawitz's cases), and of course depends upon the condition of the other kidney, either both kidneys being crushed or the remaining kidney being unhealthy.

II. PRIMARY CARCINOMA OF THE KIDNEY.

The patient, J. P. Bakken, a man of 30, came from Red Jacket, Michigan, in April, 1888, and gave the following history: He had always been healthy, and was considered a strong and robust man; worked in a mine. Two years previously, while at work in the mine, he suddenly felt a pain in the region of the kidney and went home, was laid up for some time. A diagnosis was not made, but he had a pain in that side, nothing characteristic that would call anybody's attention to the urine, and finally after some weeks he got on his feet again and concluded to go to his native country, Sweden, for his health. He stayed there, and one day while jumping about eight feet from a rock down to the ground below, suddenly felt a pain in the left lumbar region, and from that time there was blood in the urine. During the whole year there was blood in the urine, sometimes less, sometimes more, often very considerable quantities so as to make him rather anæmic. When he came to me he had lost strength, had not felt able to return to work for some time, and when examined the urine was mixed with blood in rather large quantities. There could be felt enlargement of the kidney, not very distinct, but still distinct enough to make it different from the other side, and, as in all cases of hæmaturia, I looked for pieces of tumor over and over again, and finally found a small shred of tissue showing round, oval and club-shaped cells that made me believe the tumor to be sarcoma. This decided an operation, which was nephrectomy, by the lumbar method. The patient became comatose the day after the operation, and died with symptoms of uræmic coma on the third day. No autopsy permitted.

The kidney shows the following characteristics: There is a round tumor on its anterior surface an inch and a half to two inches in diameter. Its smooth surface is covered by the distended capsule of the kidney. Its posterior surface bulges into the pelvis, the upper part of which is perforated by a sessile, polypoid projection of the tumor. The apex of this projection is rough and jagged from destruction of the mucous membrane, shreds of uncovered tumor-tissue protruding from the surface and being the source of the hæmaturia. A transverse section through the tumor shows irregular cavities in the centre filled with coagulated blood, in one instance so near the surface as to give the sensation of fluctuation. Microscopical examination shows the typical characteristics of carcinoma, with only a slight amount of connective tissue and large alveoli, lined and filled with large round and polymorphous cells; these cells have large round or slightly oval nuclei surrounded by a large granular protoplasm or cell body.

I will say a few words about primary carcinomas of the kidney in connection with this case. Carcinomas as well as sarcomas are usually found at two different periods of life, viz: from 1 to 10, and from 50 to 70 years. Carcinomas are unilateral and most common on the right side. They are more common in men than women, in contradistinction to sarcomas which are more common in women. Heredity is doubtful, but a congenital origin seems to be plausible in the carcinomas of children. Traumatism is not uncommon.

As to the anatomy, there are some points which are new in the literature, and which P. Wagner, in a recent article, has called attention to.² It was usually supposed that carcinomas originated from the epithelial cells of the urinary canals, but a number of carcinomas were found in which the cells did not look like urinary epithelial cells at all, but did look like the large cells in the supra-renal capsule. Then it was demonstrated by Klebs and Grawitz that erratic islands of supra-renal capsule tissue were found in the kidney substance near the capsule. It is therefore likely that many carcinomas having this kind of cells develop from these islands.

Clinically we may distinguish between a more benignant and a more malignant form of carcinomas. The relatively benignant form is of slow growth; may remain stationary for years, has late metastasis or not at all and is always unilateral. The average duration of the disease in adults is from one to two years; one of Wagner's cases lasted seven years and a half. The malignant form is characterized by rapid growth, softness of tissue, early diffusion and early metastasis, is common in children, where in a few months growths of enormous size are formed. Cystic

softening of the centre and hæmorrhage within the tumor is common. Carcinomas often open into the pelvis, as in the case here described causing hæmaturia, but in cases of this kind it is rare that fragments of the tumor are loosened and found in the urine.

The symptoms are naturally similar in carcinoma and sarcoma. The tumor is always found later in the disease, and may attain an enormous size, especially in children. It is often nodular, with fluctuating areas corresponding to cysts or hæmatomas within the tumor. Out of fifty cases, Ebstein found a palpable tumor noted in forty-seven, the symptoms thus being absent in only three cases. Hæmaturia is rather a common symptom; it is natural that there should be blood in the urine as soon as a tumor, carcinoma or sarcoma, opens into the pelvis of the kidney and the covering mucous membrane is destroyed by pressure, atrophy and hæmorrhage. It is quite possible that the presence of urine on the surface of such a tumor makes hæmorrhage more common by washing away clots. In a collection of seventy-five cases of adults with carcinoma, Rohrer found hæmaturia in twenty-three. In fifty cases of children, Leibert found hæmaturia in nineteen. Ebstein, in fifty cases of all ages, found hæmaturia in twenty-four. The origin of the hæmaturia is almost always from the carcinoma when it has perforated into the pelvis or ureter. Rarely, it may come from the other non-carcinomatous kidney. In a case described by Kühn, he found in the pelvis of the right non-carcinomatous kidney a teaspoonful of blood, and a coagulum in the ureter. He believes the hæmorrhage due to over-distension of the glomeruli from over-work of the organ. The hæmaturia is sometimes slight, sometimes profuse. It is usually found in the beginning of the disease, according to Leibert in two-thirds of the cases of hæmaturia, ceases after a while and does not reappear in the later course of the disease.

As to the degree of hæmorrhage: it is rarely so profuse as to prove fatal. It is not uncommon that, as in this case, the hæmorrhage is started by traumatism. Sarcoma is said to be less commonly followed by hæmaturia than is carcinoma. Neumann gives as the cause of this that sarcomas have less tendency to open into the pelvis than carcinomas. Hæmorrhage rarely occurs in the beginning, then ceases, then recurs towards the end; still more rarely does it occur towards the end and not in the beginning. Albuminuria is seen sometimes independent of hæmaturia. The presence of pieces of tumor in the urine is not a very valuable diagnostic sign because they can seldom be found. The mistake that I made here from the cells which I thought to be sarcoma, is one that Rosenstein has pointed out. Small dislodged pieces of surface epithelium from the pelvis of the kidney, with its club-shaped cells, may

² Casuistische Beiträge zur Chirurgie, Deutsche Zeitschrift für Chirurgie, Band 24.

look like and be mistaken for sarcoma. A safer method of diagnosis is to make an exploratory aspiration from within the tumor and get out a little piece of tissue in the hypodermic syringe which will often give a piece large enough for diagnosis. Pain is often absent. When present, besides having its seat in the region of the kidney, it radiates towards the ribs and down the femur. Pain is not only commonly absent, but it is not characteristic of malignant tumors as compared with an inflammatory condition of the same region. The diagnosis between sarcoma and carcinoma is an ideal one, as the treatment is the same. No symptoms exist to make such a diagnosis outside of anatomical means.

As to the treatment by extirpation, it was said by Gross two years ago that the results are so miserable that extirpation of the carcinomatous kidney should be entirely given up. Sarcomas in children should not be extirpated, and the only malignant tumors of the kidney where extirpation should be permitted are sarcomas in adults, especially in women, and more especially in floating kidney. It is possible that when an earlier diagnosis can be made, earlier operation may make the prognosis better. The majority of surgeons, in Germany at least, believe that this will be so. The arguments in favor of operation are that the disease is usually unilateral, both kidneys being diseased in only 10 per cent. of the cases (Wagner), and further that the relatively benign forms have a slow growth and late metastasis. Rohrer in 115 cases found none in which the peripheral lymph glands were invaded.

The prognosis of extirpation is grave in young children who have slight power of resistance against extensive operations with great loss of blood; the prognosis is also grave when the operation is performed so late that the patient is already cachectic. Gross collected forty-nine cases of nephrectomy for carcinoma or sarcoma: thirty died during or shortly after the operation; of the remaining nineteen, ten died within a few months from continuance of the growth, and six, all of which were cases of carcinoma in adults, lived only from one and a half to five years. The prognosis of the operation was most grave in children: of sixteen children, nine died from the operation, four shortly after, and three were not afterwards heard from.

As to the method of operating: Laparotomy is more dangerous than lumbar extirpation, the respective percentage of mortality being as 64 to 45. Consequently the lumbar operation should be always preferred when the size of the tumor will permit. The longitudinal or oblique incision gives too little space, therefore a T-shaped incision is preferable. Von Bergmann has recently proposed an interior oblique incision, the same as for ligature of the aorta and common iliac, pushing the peritoneum inward from the anterior surface of the tumor.

III. RENAL CALCULUS.

The third specimen is a stone from the pelvis of a kidney. The patient, Mrs. P. *et.* 30, from Dakota, had always been healthy with the exception of chronic indigestion for which she had been under medical treatment off and on for years, until a year ago last March, when she noticed intermittent pains in the right side soon followed by a whitish sediment in the urine. She gradually lost strength and flesh, and the attacks of pain, often running down the right leg, became more frequent and more severe.

On admission to Emergency Hospital she looked exceedingly pale and emaciated, a swelling seven inches long and four inches broad was found in the right side of the abdomen, extending from an inch to the right of the umbilicus, outward and backward into the region of the kidney. The tumor was somewhat tender to the touch indistinctly fluctuating and slightly movable, below and separated from the liver. An exploratory puncture in the lumbar region disclosed the presence of stone and brought out pus. Pulse 100; temperature 101°. On January 21, I made nephrotomy by lumbar incision. When the surface of the kidney was reached fluctuation was distinctly felt through a thin layer of kidney tissue. This was divided by Paquelin's cautery, and a pint and a half of fetid pus evacuated. Digital exploration revealed three stones the size of a hazelnut, and a large one two and a half inches long with projections corresponding to the calices of the kidney, slightly movable, but still so firmly imbedded that it was necessary to divide it by crushing. In attempting to remove the pieces it was still found difficult to dislodge the projections into the calices without tearing through the thin layer of cortical tissue. For fear of breaking through the surface of the kidney into the peritoneal cavity, it was found necessary to enlarge the opening on the convex side of the kidney to about an inch and a half so as to bring out the fragments without too dangerous manipulation. The irregular cavity was washed out with boracic acid through two large drainage tubes.

In the course of five weeks the suppuration diminished, temperature became almost normal, the patient improved in general health, and toward the end of April had gained thirty-five pounds in weight. There still remained, however, a purulent discharge through the drainage tube around which the wound had contracted considerably, and there was still some pus in the urine. On the supposition that either the drainage was insufficient or that some portion of the stone still remained, the fistula into the kidney was reopened on May 9. In the cavity, now much contracted, a small amount of gravel was found, and in the upper part of the kidney, an abscess cavity the size of a walnut, apparently not connected

with the pelvis. No stone was found here. Drainage and packing with iodoform gauze. Since that time the discharge has diminished, but a fistula still remains: the urine has become clear, but still contains a small amount of pus.

I shall make no further remarks on the subject of nephrolithotomy as Prof. Billings is going to discuss the subject and exhibit the specimens of a second case, operated upon by me about two weeks ago.

TREATMENT OF ACUTE LOBAR PNEUMONIA.

Read at the Fifth Annual Meeting of the Fifth District Branch of the New York State Medical Association, held in Brooklyn, on May 28, 1886.

BY J. G. TRUAX, M.D.,
OF NEW YORK.

The writer will not detain you very long to-day. His intention is not to give a complete history of the treatment of lobar pneumonia; that can be found in any of the late text-books, but rather to give an account of the particular kind of treatment which has proven to be the most successful in his experience. Before doing this, perhaps it would be well to describe some of the different kinds of pneumonia, only one of which will be considered in this paper, namely: acute lobar or croupous. The signs by which this disease may be recognized are these: Severe chill, pain, prostration and cough, nausea, rise of temperature, fine crepitant râles (not always present), sputum sticky and streaked with blood, albuminuria present in a large proportion of cases—about 50 per cent. Great trouble in breathing, a quickened pulse, sometimes very rapid. There may be very marked dulness on percussion and bronchial breathing. Vocal fremitus increased. When this last condition is present on left side, it is of considerable importance as a diagnostic sign.

The disease for which acute lobar pneumonia is most liable to be mistaken is secondary lobar pneumonia. The last-named disease is more insidious in its beginning. There is less trouble in breathing, chill frequently absent, little or no pain, average temperature not so high. Bronchial breathing and dulness are the most decided symptoms. Expectoration scanty, crisis sooner than in acute lobar pneumonia.

The other varieties of pneumonia need not be described, to name them will be sufficient. They could hardly be mistaken for either of the diseases just mentioned. They are known as bronchial, lobular or catarrhal, embolic lobular or septic, interstitial of heart disease or chronic, hypostatic or lung congestion.

Within the last few months the writer has attended fifty cases of acute lobar pneumonia. The etiology and clinical history he has been able to carefully study in these cases while alive, and to

make autopsies upon the thirteen who died. It will be unnecessary to give a detailed history of each of the fifty cases and the treatment in each particular case. To do so would not be in accordance with the scope or object of this paper, but for purpose of instruction two cases will be taken, A and B, which will represent the conditions requiring the greatest variation in the treatment of acute lobar pneumonia.

A is a patient in middle life, medium size and fairly well nourished. When first seen he gave a history of chill, pain in the chest, prostration and cough; respirations and pulse more frequent than in health, sputum streaked with blood and scanty; temperature 2° or 3° above normal. A physical examination reveals a crepitant râle, some dulness on percussion over lower lobe of either lung, and bronchial breathing. There is no albumen in urine, no delirium, pulse rarely getting above 100. Crisis takes place in from five to ten days. This class of cases comprise about half of all the pneumonic patients that come under the care of the physician. He can give full play to any fancy in the treatment of these patients. They will nearly all recover no matter how treated.

B represents another condition, present in many of those unfortunate enough to be afflicted with this dreaded disease, which, while there is not so much difference shown by a physical examination, the clinical history differs widely, and to conduct to a favorable termination, will require the care and skill of an intelligent physician. Here we find albuminuria and delirium almost always present, temperature rises to 104° or 105° , pulse 120 to 140, great embarrassment of the respiratory circulation and consequently a labored heart action.

Is there anything to be done which will relieve the patient of these aggravated symptoms? The object of this paper is to teach that generally it can be done and many lives saved. The writer has no new theory to advance; his only object is to revive a very old one (with some few modifications), which has generally fallen into disuse; or, more properly speaking, gone out of fashion. Almost all kinds of treatment, other than venesection, have been tried by the writer to relieve the heart, when obstruction to the pulmonary circulation was very great, and death from heart failure imminent, but with no great success. He had lost five patients in succession (all Italians) from this cause, none of whom had more than one lobe of one lung affected, and all having the appearance of being sturdy if not robust men. Not having written a book on any treatment of this disease, the writer did not hesitate about changing his when circumstances seemed to require it. To take from such patients venous blood, thus relieving the right heart, and to some extent lung congestion, appeared to the writer to be rational treatment. Experience has proven it

to be so. The next five patients coming under his care, who seemed to be in great danger of dying from heart failure, were bled. They all recovered, all the aggravated symptoms improving immediately after bleeding. Experience has taught that antifebrin and quinine in small doses after bleeding would control the temperature and pulse for a long time. Given in large doses before venesection in these cases, it produced almost no effect. Hoping that it may prove interesting, the writer will now read a condensed report of the five patients bled. Such portions of the histories only as will show the condition the patients were in at time of bleeding, and the effect of the treatment, have been taken.

Case 1.—Joseph Albindo, æt. 25, born in Italy, married, occupation laborer. Admitted into the hospital March 14, 1:30 P.M. Temp. 105°, pulse 112, resp. 53. Great dyspnoea and painful respiration, face and neck very much congested. Physical examination showed him to have pneumonia of lower lobe of left lung. Patient given 10 grs. of calomel, 20 grs. of quinine and 5 of antifebrin. The medicine apparently having no effect three hours after given, 16 ozs. of blood were taken from right arm. The patient breathed easier at once; he had a slight chill, which was soon checked by stimulants. Temperature fell gradually until next day, when it was 102°. At no time afterwards did it get higher. Discharged cured April 4.

Case 2.—Louis Berlitchio, æt. 45, native of Italy, laborer, married. Admitted March 26. Had been sick three days, was first taken with a chill; at time of admission complained of pain in right chest, and had a cough. Physical examination revealed dullness over lower lobe of right lung and part of middle, bronchophony, crepitant râles and increased vocal fremitus. Temp. 101°, pulse 108, resp. 36. The next morning temp. 103.8; next afternoon temp. 104°. Urine examined; color red, reaction acid, specific gravity 1015, albumen 10 per cent. Patient given sponge bath, quinine and antifebrin. March 28, two days after admission, temp. 104°, pulse 142, resp. 42. Pulse full and bounding, respirations superficial and painful. The median basilic vein of right arm was opened and 16 ozs. of blood taken. Patient was comfortable in the evening. Dyspnoea not so great and the pulse not so rapid. March 29, temp. 104.6°, quickly reduced with 3 grs. of antifebrin. March 30, temp. did not go above 102°. Nothing given to patient but milk. March 31, temp. 103°; given 3 grs. of antifebrin. After this the patient did well and was discharged cured April 12.

Case 3.—Guiseppe Posatti, æt. 28, native of Italy, laborer. Admitted to the hospital July 15, 1888. This patient was not very robust, looked as if he had no blood to spare. Physical examination revealed the signs of pneumonia of lower

lobe of left lung. His temperature was not very high, but there was great dyspnoea and a very rapid pulse. After having been given for twenty-four hours the usual remedies for improving the action of the heart, with little effect, the patient was bled. Owing to his anæmic condition only 11 ozs. of blood were taken. The distressing symptoms passed away at once. Patient made a good recovery, and was discharged cured in less than one month from time of admission. Bleeding was contraindicated in this case by all the rules laid down in recent text-books.

Case 4.—John Matza, æt. 24, native of Italy. Admitted into the hospital February 1, 12:30 P.M. This patient had pneumonia of lower lobe of left lung, and phthisis of upper lobe of right. His temperature went up to 104.6°, pulse 140, and respirations 44. We did not bleed this patient until after stimulants failed to keep up the action of the heart. The heart action had become very weak. Thirteen ozs. of blood were taken from right arm. Patient improved after bleeding. He left the hospital one month and twenty-four days after admission cured of his pneumonia.

Case 5.—John Grady, æt. 31, born in this country, single, laborer. Admitted September 24, 1888. Gave upon examination the physical signs of pneumonia of both lungs. At time of admission patient was suffering from great pain and dyspnoea. Temp. 104°, pulse 118, resp. 40. He was put to bed and given a sponge bath, which reduced slightly the temperature. 6 P.M., three hours after admission, temp. 105°, pulse 136, resp. 46. He was given at this time quinine grs. x, antifebrin grs. iij, poultices applied to chest, milk diet. This treatment continued until September 30, when the following record is found on the history book: "Patient has been delirious all day, had to be constantly watched to prevent him from getting out of bed, is very thirsty, calling for drink all the time. Given over 4 pints of milk during the day. Urine examined shows 20 per cent. albumen. The patient has a full, bounding pulse, there is great dyspnoea. At 3 P.M. 17 ozs. of blood were taken from right arm. Patient seemed weaker afterwards, but the dyspnoea had disappeared and he rested much better through the night. Twenty-four hours after bleeding temp. 101°, pulse 76, resp. 32. Patient made a good recovery and was discharged cured in about four weeks from time of admission."

The writer would suggest the following general rules for the treatment of acute lobar pneumonia: When patient is first seen, unless contraindicated, a brisk cathartic. Should there not be much impairment of the pulmonary circulation or a very high temperature, a liberal milk diet will be sufficient; or, in other words, the treatment should be expectant. When great dyspnoea, high temperature and a rapid, bounding pulse are present, something must be done. To relieve these symptoms

the patient should first be given quinine grs. x, antifebrin grs. iij, every four hours (unless patient improve sooner), until at least 30 grs. of quinine and 9 of antifebrin have been given. If the patient does not improve under this treatment in twenty-four hours, dyspnoea, rapid pulse and high temperature still remaining, venesection should be performed, and enough blood taken to relieve patient.

Experience has led the writer to believe that bleeding will save many patients when all other means would prove futile.

17 E. 127th St., New York City.

HIGHER GRADUATE INSTRUCTION AND SPECIALISM IN MEDICINE.

BY LAWRENCE TURNBULL, M.D., PH.G.,
OF PHILADELPHIA.

Delivered at the Opening of the New Howard Hospital Building, Broad and Catharine Sts., Philadelphia, May 23, 1889.

Is this instruction required? Examine the men who are yearly sent out of our Medical Institutions, all over the country, with their diplomas, and you will find they are sadly deficient in the practical knowledge to fit them to take the lives of the community in their hands.

Proof of this is not wanting: a few questions addressed to them will convince the most sceptical of their utter ignorance of some of the most essential facts, which are always considered requisite to make a correct diagnosis. The extreme awkwardness with which they handle delicate instruments, shows at a glance that they are not familiar with them. A still more positive proof is afforded, by the best men of the class, being willing and anxious to undergo a competitive examination for the Navy, Army, or Hospital appointment, so as to afford them the opportunity of practical instruction, which is of so much value in the profession. How few, alas, are these opportunities to the larger number who apply, and how dishonorable in our schools of medicine to grant diplomas to hosts of graduates who are lacking practical technical education, and still more, manual training: who must enter practice, and find little or no success, drift into something else, or become depressed in mind, at their lack of the requisite knowledge, losing their patients, because unable to make a correct diagnosis and follow it by successful treatment. These men, many of them, poor in pocket, but rich in honorable intentions, feeling their great need, as soon as they are able to save a little money, have to come again to the great centres of medical knowledge for the practical instruction, which they should have acquired before receiving their certificate to practice.

What is wanted in our Medical Schools? There are always young alumni of the various schools,

who having little practice and plenty of time on their hands in a large city, devote themselves to special branches of medicine, and acquire a thorough knowledge of the same in order to teach, and are glad to be connected with their Alma Mater. These men should receive, as an equivalent for their work, the title of Clinical Professors, and in conjunction with some hospital or dispensary service, should teach, a number of months in the year, to limited classes designated by the Faculty.

NUMBER OF LECTURES.

There should be from three to six lectures, clinics or private classes at the same time, and most of our large buildings could be so altered as to provide accommodations for the students. Prior to their coming, it would be of much service to them if they could acquire some knowledge of the living languages, such as French and German, and botany, natural philosophy and zoology.

What the Junior students should do before they come: First. Much time should be given to anatomy, the study of bones, dissecting dead animals and living plants. Second. Demonstrations upon model or manikin, or the dead subject, so as to be able to point out and determine, first, the color, form and size of every organ of the body, and its position in relation to other organs. Third. To attend a certain number of lectures on chemistry, then, to perform all the ordinary simple experiments in chemistry, in the laboratory; testing the purity of drugs, animal fluids, their toxicological relations, etc. Fourth. Lectures on *Materia Medica*, and by handling, smelling, and tasting every article employed in medicine; not only when properly labelled and named, but to determine the name by the form, taste and smell, when only numbered. All of the manipulations in pharmacy and pharmaceutical chemistry in the laboratory. In the summer months, the teacher or clinical professor of *materia medica*, should form a class for the study of practical medical botany, and describe each specimen and dissect it under the microscope. The assistant professor of chemistry, should teach medical physics, including heat, light, sound, electricity, thermometry, etc.

What the Senior or Graduating Class should do. *Pathology.*—First, of animals, by handling every organ and dissecting it, and then of men, and the various natural and then abnormal products, and rare forms, by means of models.

Practical Medicine should be taught by lectures on diagnosis and memorizing the chief points of the most ordinary diseases, symptoms, palpation, percussion and auscultation.

Surgery.—First, minor surgery, applying bandages, bleeding, cupping, applying leeches, opening abscesses, vaccination, removing foreign

bodies, making of poultices, applying hot and cold lotions, etc.

Major Surgery. Operations under a clinical assistant, by performing every thing of importance.

Obstetrics.—The care of the woman prior and subsequent to confinement. Mode of arranging the bed in confinement, position, etc. Touch and mode of determining the position of the fetus. Thorough knowledge of the various positions of the fetus in utero. Various steps of delivery. Applications and use of catheter, and forceps on the manikin, etc., and attendance upon one to three cases of normal and abnormal labor, with use of forceps and catheter, under care of assistant.

Care of the women after confinement, diseases of the nipple and mammary glands. Also care and treatment of phlebitis and puerperal fever.

Gynecology.—Study of symptoms treatment of amenorrhœa, and dysmenorrhœa, leucorrhœa, and anæmia. Diagnosis of ulceration of uterus, ovarian, fibroid, polypus, and malignant disease, with operations for the same.

Therapeutics.—This is one of the most important subjects in the whole curriculum of study, demanding the most thorough and careful consideration on the part of both teacher and student.

The class should be so arranged, that each individual will be able to study the action of all drugs and medicines on animals and man; first on the animal and then on the man; and every medical school should provide animals for that purpose. Especially should be tested all powerful alkaloids, as atropia, morphia, pilocarpine, aconite, cocaine, etc., and be able to see the antidotes applied. Testing of all the secretions and excretions in various diseases, urine, blood, bile, feces, etc., so as to tell at a glance if the secretions be normal or abnormal.

The graduating class or post-graduate, wants to receive the opinions, and newest practical ideas of the specialist in mental and nervous diseases; of laryngologists, or throat diseases; ophthalmologists, or eye system; and otologists in diseases of the ear.

He requires instruction in their various methods of the application and manipulation with instruments, use of light, etc., so as to examine every part of the human body, and by a system of exclusion, find out the most obscure disease. These should be supplied with but little extra expense to a graduate in medicine of a three years' graded course.

Another important matter is, careful and systematic training in the administration of anæsthetics:

This should be given to every medical student, as so much depends upon the administrator—in some cases almost more than upon the operator. At how many medical schools are any but the barest attempts made to give instruction in a sys-

tematic manner, on a subject which I venture to think is not the least important in the curriculum?

We now come to the last part of our subject: Specialism in Medicine.

Specialism is one of the legitimate developments of medicine, and the great strength which to-day is manifested in special organizations shows how well the founders of this hospital were truly alive to the most progressive ideas. Look at the growth of medical knowledge during the thirty-six years of its existence in this institution. It has become so great that our mind cannot master, much less employ the knowledge in the practice.

As a recent writer so well expresses it: "There are no admirable Crichtons in our art. The genius of a Sydenham would shrink in despair before the immense masses of medical lore accumulated since his day. We read with astonishment of the acquirements of Dr. John Mason Good, who, to the reputation of a polyglot, added that of one of the foremost practitioners of his age. It is universally acknowledged that the men of one idea, those who confine their attention to one thing, be it a business or a science, are the men who succeed, who represent the progress of the age, and whose names posterity will not willingly let die. If we could imagine a physician thrown into a Rip Van Winkle sleep of say but ten years, and then recommence the practice of medicine, he would be astonished at the progress in all branches of the art. He would feel like the mouse which thought his chest was all the world, was astonished when he stood upon the hill and looked out to see what a great world lay beyond him. An oculist once observed with apparent satisfaction that many people no longer consult the family doctor about their eyes, but went at once to the oculist, as they would to a dentist for their teeth. Some regard this custom as objectionable, but it is entirely correct. The oculist will know the most about the eyes, and the doctrine that the patient should first go to a general practitioner, to be by him referred to the specialist, sounds very pretty, but it is unreasonable. Specialists of any standing in large cities are generally about equal in abilities, and the patient is just as likely to make a correct choice as the family physician." (Leffman.)

"Every year, as the physician becomes better educated, is his field of labor enlarged. Some years since the application of the obstetrical forceps was regarded as an operation requiring a consultation; now every recent graduate considers himself capable of performing it. All doctors should be able to prescribe the proper glasses for simple hypermetropia, and apply the uterine dilator in cases where it is indicated. These methods of treatment are supposed to belong especially to the oculist and gynecologist.

What is this extension, however, but an admis-

sion of the advantages of specialism? Why is the use of these instruments advised? Because these applications in the hands of specialists have shown such beneficial results that the general profession dares not overlook them if it would be true to its great trusts. Imitation is the sincerest flattery, and so far as the general practitioner follows the specialist, he unconsciously approves him."

In a recent discussion on this subject, Dr. Edward Jackson expressed some logical views, as follows:

"It has been said that the large number of specialists might be ascribed to the ignorance of the general practitioner. I would state this differently, and call attention to a view of specialism which I think is not sufficiently considered. A young man who has spent a few months in some eye hospital, concludes to take up the specialty of diseases of the eye, and goes into some large town in the interior of the country, where specialism is unheard of. He is consulted by patients who have become blind from glaucoma, losing the precious time when relief was possible, by advice of the best practitioners of the place, they must await the ripening of cataracts that never existed. He will find other cases—for instance, of refractive errors—which have been improperly treated or not treated at all. Cases of this kind will give him reputation with the laity, but will probably make enemies in the profession and raise some outcry against specialism. Now in such a town, the fact is, not the general practitioners are ignorant, but that there are no general practitioners. Those calling themselves general practitioners have been practicing specialism in its commonest form—that is, the form in which the practitioner devotes his attention especially to acute inflammatory diseases, fevers, obstetrics, and one or two other subjects, and ignores very many important branches of medicine. This is the form of specialism that has taken the firmest root and spread most widely; and specialism, so called, is merely the necessary growth of this, and is, to a certain extent, a recuperative reaction. This primary, widespread, and worst form of specialism arises from defective medical education. The crowded college curriculum does not adequately provide for certain departments of medicine which are of as real importance as any to the truly general practitioner."

And it is fair to ask—can a man be an educated physician and yet be ignorant of the use of the ophthalmoscope. Take, for instance, optic neuritis, and cerebellar disease, retinal hæmorrhage and renal mischief, retinal congestion and neuritis in pregnancy, characteristic retina of leukæmia. An examination of the retina might save a life. How many unfortunate might escape a world of drugging, if the practitioner could recognize the effects of astigmatism in the headache, the dizzi-

ness, the inability to work—symptoms so often referred to the stomach—all corrected by suitable glasses!

In the case of otology, let me enumerate some of the blunders I have known to be committed. Polypus has been mistaken for abscess and *vice versa*; the membrane destroyed in attempts to remove a foreign body which was not present; cerumen syringed for heroically, when not a particle of cerumen was there; the *membrana tympani* supposed to be absent and an artificial membrane advised to be worn, when the membrane was intact; ears lost, in, and after scarlatina, from want of treatment by paracentesis; mastoid abscess and periostitis, the result of neglected discharge, which was permitted to exist under the practitioner's advice that to "meddle with a discharge from the ear was dangerous." To those alone who do a large aural practice are the errors known which are fallen into in the simplest cases from a want of as much otological knowledge as one might gain in the extern department of our hospital in a single day. The study of the ear and throat is naturally allied. The naso-pharyngeal tract, so frequently affected simultaneously with the ear, requires special attention at the hands of all those who are anxious to know anything of diseases of the latter. There is no simple instrument to learn the application of, or at least to make one's self proficient in the diagnostic value of, than the laryngoscope.

To treat blindly every case of aphonia, ignorant of its cause and the pathological states which gives rise to it, when we can readily satisfy ourselves of the condition of the larynx with the laryngoscope, partakes strongly of quackery. The distress caused to the patient in using the instrument, and the discomfiture of the surgeon in the attempt, is simply the result of the waste of some little instruction, which would prevent the bungling and awkwardness of an uneducated hand.

In order to properly follow and develop any one of the specialties in medicine, the medical man must have a thorough training and experience as a general practitioner and then gradually devote his mind and body to the special study of one department, which he intends to make his life work.

Now a word or two in regard to our institution. Of the medical men who first acquired fame in this institution and have now passed away, we cannot help noting the names of James Aitken Meigs, distinguished as an Ethnologist and Physiologist, and of Samuel W. Gross, who performed his first important operation in this hospital. Of old residents and physicians who were connected with us and are now practicing their profession with credit to themselves, the public, and our institution, we would mention a few of them as Drs. C. P. Turner, O. H. Allis, Wm. H.

Parrish, C. S. Turnbull and many others. Some misapprehension has occurred in reference to our incurable department that we have placed so prominently on the front of our building.

The Howard was the very first to bring this important subject to the attention of the profession and the public; fortunately at that early period it languished for the want of adequate funds. It prevented us from erecting a large building and bringing together a mass of suffering humanity, who when they entered were never to return into the world well beings, each tending to make the other unhappy and all hopeless. It is well known from experience and experiments that no two consumptive patients, or cases of cancer, can be in the same ward without much discomfort to each and others by their cough and the disagreeable odors common to the incurable department. Hospitals for consumptives and cancer, both in this country and in Europe, have not proved a success. The home, be it ever so humble, of each sick and incurable individual is the best and most happy place, when supplied with the proper medical attendance, food, and now and then a little money to tide over difficulties. It is in this manner, we propose to carry out the incurable infirmary department. When we are able by the generous gift of some friend, we mean to purchase a number of single small houses, to accommodate those who are so unfortunate as to have *no home*. Some of those who hear me, who have the means, may be twice blessed by giving of their abundance to this department.

HYSTERECTOMY FOR LARGE FIBROMYOMA.

BY D. BENJAMIN, M.D.,

SURGEON COOPER HOSPITAL, CAMDEN, N. J.

H. M., æt. 30, living in the southern part of the State, came to me on the 24th of March, 1888, suffering from a large abdominal tumor, which, she stated, her physicians called an ovarian tumor. I obtained the following history: Her mother died of erysipelas; one sister died with cerebro-spinal meningitis. Patient's past condition was stated to have been moderately healthy until last summer, when she commenced to lose flesh; at this time there was noticed a slight enlargement of the abdomen, which was attributed to dropsy.

In October, 1887, she was examined by a physician, who stated that there was a tumor in the left ovarian region, then about the size of a fist. Two months afterwards she was subjected to another examination, and the tumor was found to have increased in size to that of a child's head. No history of any injury to this region could be obtained. Her menstrual flow had been regular,

sometimes profuse, had skipped one month, which she attributed to a cold.

She began to suffer from vomiting and constipation, and occasional abdominal pains. These symptoms had constantly grown worse, until almost every meal was vomited, and constipation became more and more obstinate, so that powerful purgatives had to be administered, but were losing their effect, and symptoms of obstruction were becoming marked.

She had lost fifty pounds on her weight within a few months, but as she had been previously inclined to embonpoint, her emaciation was not extreme. On palpation through the abdominal wall the tumor appeared symmetrical and mobile, did not feel so hard as is common with fibroid tumors, nor so soft as a cyst; was not nodular, felt very much like a pregnant womb in the early part of the ninth month. Fluctuation could not be positively demonstrated. Percussion sound dull, except a small area in each flank.

Vaginal examination showed cervix drawn up, and enlargement in Douglas' pouch about the size of a retroverted womb. Rectal touch gave no additional information, flexible urethral sound passed into os uteri about two inches, taking a forward direction; pregnancy having been eliminated by the examination, a diagnosis of solid, or semi-solid tumor, involving womb, could be made, but the exact relation of the ovaries to this tumor was not clear, and exploratory incision was advised, with a view of ascertaining the exact relation of the tumor to the pelvic organ and the possibility of its removal, with the understanding that any beneficial operation that would seem feasible, should be proceeded with. Accordingly, on the 29th of March, patient was etherized; the usual incision was made in median line, and surface of tumor exposed. Tumor was quite elastic and of a dark, muscular flesh color, and wedged so tightly in the superior straight of the pelvis, that only one ovary could be reached (the left, which was enlarged). Adhesion being slight, the incision was extended upward, with scissors, sufficiently to enable the upper part of the tumor to be reached, which was free, but in contact with the stomach and liver. The incision was then extended upward and downward sufficiently to enable the tumor to be delivered forward through the abdominal incision.

Both ovaries and Fallopian tubes could be easily reached, while the large tumor was held upward out of the abdominal cavity by an assistant. The pedicle could not, at this stage, be thoroughly examined. The right ovary was found crowded down into Douglas' pouch, and was enlarged to about the size of a hen's egg and roughened on the surface.

The right Fallopian tube was also much enlarged; the left Fallopian tube was about double the normal size and adherent. Both ovaries and

both Fallopian tubes were carefully ligated and cut away. The exact relation of the base of the tumor to the womb could now be clearly made out, and it was apparent that room enough could be made above the insertion of the vaginal wall into the cervix to remove the tumor and body of the womb (which was thoroughly uniformly fused), without necessarily wounding ureters, bladder, or other pelvic organ. I then determined to remove the entire tumor and womb, since to return it to the abdominal cavity would have been to have left her in almost as bad a condition as before the operation, with respect to the obstruction and other difficulties which the tumor caused, and at the same time be little less dangerous to the patient's life than complete hysterectomy. I then carried the incision downward as closely to the pelvic bone as the bladder would permit, ligated each of the round ligaments in two places and cut between, applied Koeberle's clamp and cut away the tumor and womb. The stump was at least three inches in diameter. Tumor was about thirty inches in circumference. After all bleeding points had been properly secured, and all clots removed from the abdominal cavity, the bowels and peritonem were thoroughly washed out by pouring three or four gallon pitcherfuls of warm water into her.

The omentum, which had been lying on a towel, was returned and arranged over the bowels. The pedicle was fixed in the lower angle of the womb and incision closed with silk sutures, at intervals, of less than an half inch. Wound was dressed antiseptically and patient placed in bed.

Temperature, which had been normal previously to the operation, was taken three-quarters of an hour afterwards and found to be $97\frac{1}{2}^{\circ}$; at 4 P.M., $100\frac{4}{5}^{\circ}$. The second day, at 7 P.M., it reached $100\frac{2}{5}^{\circ}$; pulse, 128; breathing, 28. Third day, 7 A.M., temperature, 101° ; 7 P.M., temperature, $101\frac{2}{5}^{\circ}$; pulse, 116; breathing, 24. Fourth day, 7 A.M., temperature, $99\frac{3}{5}^{\circ}$; 7 P.M., $100\frac{3}{5}^{\circ}$. Fifth day, 7 A.M., temperature, $99\frac{2}{5}^{\circ}$. Catheterization stopped on account of cystic irritation. Patient constantly improved without any untoward symptoms, and was discharged in six weeks after the operation. Clamp came off on the twenty-third day. Has not vomited since the operation; has had no pain; all functions are normal. States that it is the first time she has felt well for four or five years. Has returned to her home in the country, with rosy cheeks, full of life, and at this date, May, 1889, is in perfect health. Has not been sick a day since the operation, and is glad that she parted with her womb and ovaries.

In determining the value of the operation of hysterectomy to humanity, it is important that all cases should be reported, as I found the literature on the subject so meagre at the time of the above operation, that reliable data could not

be obtained in this country. The operation had never, so far as I can learn, been performed in New Jersey, but as hysterectomies are becoming more frequent and successful, ample statistics will soon be forthcoming.

AN UNUSUAL IDIOSYNCRASY ATTENDING THE USE OF ERGOT.

BY D. W. PRENTISS, M.D.,

OF WASHINGTON, D. C.

The patient, a brunette 41 years of age, had always been in good health excepting uterine disorders; married twenty-two years, never pregnant. Has had uterine fibroid tumors for eight years. Previous to 1873 had three attacks of pelvic cellulitis. The tumors were discovered in 1881, since which date she has taken ergot almost constantly, either in form of fl. extract or by suppositories, to control the menorrhagia. The fluid extract was given in doses of from 15 drops to a teaspoonful three times a day for eight years. The effect was very decided in controlling the hæmorrhage, the larger dose being used when the hæmorrhage was severe, and the smaller dose in the interval.

The tumors became smaller under its use and the patient's life was rendered more comfortable, but it produced a peculiar effect to which I wish to call attention, never having observed the same before. This was the same whether taken by the mouth or by suppository.

This effect was uniform and very marked, and I have not seen it referred to in the literature of this drug. It was characterized by a peculiar depression of spirits with hysterical phenomena, and was more marked when full doses of the fl. ext. were taken, less marked when using the suppositories of ergotin. After taking ergot for three days she feels like crying all the time; then, on the fourth day, is ill-tempered and displeased with everything and wants to quarrel; will lie in bed and cry all day. All this while her natural disposition is just the opposite—even-tempered and exceptionally pleasant.

The family soon came to recognize this state of mind and respect it accordingly. Husband and servants were careful not to aggravate it, and even the little adopted daughter would say, "Mamma has been taking ergot, don't notice her."

The effect here noticed occurred constantly following the ergot, and was undoubtedly produced by it.

PAINTING FLOORS.—A French writer observes that painting floors with any color containing white lead is injurious, as it renders the wood soft and less capable of wear. Other paints without lead, such as ochre, raw umber, or sienna, are not injurious.

REPORTS FROM HOSPITALS.

SURGICAL CLINICS AT THE WESTERN PENNSYLVANIA HOSPITAL BEFORE THE STUDENTS OF THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

BY PROFESSOR J. B. MURDOCH,

SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL AND PROFESSOR OF CLINICAL SURGERY IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

[Reported by WILL. N. PRINGLE, M.D., a member of the Graduating Class.]

February 16, 1889.

AMPUTATION OF HIP-JOINT.

I have a patient to bring before you to-day who has come here seeking relief from a most grievous condition. He has traveled throughout this and other States in search of relief and hoping to be rid of his malady, but in each and every case to be turned away in despair by surgeon after surgeon telling him that there was no relief for him, and that his case was hopeless. Three years ago this man was a blacksmith and was kicked on the leg by a horse. Soon after a small lump appeared, which grew, at first slowly and hardly perceptibly, later it grew more rapidly, and within the past year it has grown with frightful rapidity, and is now so large as to keep his legs separated and to interfere considerably with his powers of locomotion. I consider this a more than ordinarily sad case. When great men like President Lincoln, President Garfield or Emperor Frederick, are stricken down and death seems inevitable, and the best surgeons of the country take up their post by their dying bed, all the world looks on aghast and cries out that men who will thus stand face to face with death are brave men—and so they are. But men like President Lincoln, President Garfield or Emperor Frederick have climbed the ladder of fame, they have attained the highest position in the gift of the people of their respective countries, they have shone in their greatest glory, they have accomplished their greatest good. Such men as these have generally passed the meridian of life, they are in the decline.

Here is a man not yet 30, comparatively a young man; strong, healthy, robust, recently married and the father of one child; prospects and opportunities for future good just looming up before him, when just in the prime of life he is suddenly stricken down by a disease, probably cancerous in its nature and as deadly in its characters as the assassin's bullet, if allowed to pursue its rapid onward progress. What will be required here it is impossible to tell; the operation is in a manner an exploratory operation—it may involve the removal of an immense tumor or it may involve an amputation at the hip-joint. The pa-

tient is reduced in strength and may not survive the operation long enough to be removed to his bed in the ward. It is with a sense of grave responsibility that I approach this operation. These are the cases that will test your skill, your knowledge and your courage. An operation is, however, the only chance that remains for the patient, and it is a duty which no surgeon should shirk. As I have said, he has consulted many physicians, and their opinions have been various. Some diagnosed abscess, others lymphoma, lipoma, sarcoma, and many other states and conditions. I am of the opinion that it is a sarcoma, or an osteosarcoma. Now sarcomata, as you know, are cancerous in their nature and prone to return, and a very good rule in surgery is that, where sarcoma attacks a bone, the whole bone should be removed.

A few years ago a lady suffering from an osteosarcoma which had attacked the femur just above the knee, applied to me for relief. I amputated the limb at the upper third of the thigh, thinking that at that point I would certainly be in sound tissue. The patient made a good recovery, but after six months the disease returned with all its virulency, and then I wished that I had removed the limb at the hip-joint. I would therefore advise you that, in all cases, where sarcoma attacks a bone, you remove the entire bone; always go to the joint next above the seat of disease. Sarcoma, as regards the form of its cells, is of three varieties, *i. e.*, the round-celled sarcoma, which is the most malignant in its nature; the spindle-celled sarcoma, which next approaches it in malignancy; and the giant-celled sarcoma, which is the least malignant. They are all, however, likely to return after removal, unless they are completely eradicated by a most thorough operation. Inasmuch as this has been diagnosed an abscess by some surgeons, and in the hope that they may be right, I will insert an aspirator needle well into it and see what we may be able to obtain. You remember that the history of this case was that at first it grew slowly but as it grew in age it increased in rapidity, and now has attained a size exceeding that of the foetal head. No fluid can be induced to flow through the aspirator, although the point of the needle is movable and feels as though it was in a cavity. I will therefore prepare to remove the tumor or amputate the limb at the hip-joint, as may be required. I elevate the limb to a right angle to the body and carefully endeavor, by stroking the skin from the toes toward the body, to drive the blood from the limb. I will apply an Esmarch's bandage the entire length of the limb, pass it around the perineum and carry it well up over the crest of the ilium. A roller bandage will serve as a compress to control hæmorrhage from the external iliac, while the other end of the rubber bandage will compress the branches of the internal iliac which have an exit from the pelvis at the great sciatic foramina.

An assistant will make steady traction on the ends of the rubber bandage. This method of controlling hæmorrhage was first introduced by Mr. Lloyd, of Birmingham, England, and has proved a very efficient method.

As I make an incision and pass my finger into the tumor I at once find a cavity with firm walls and filled with blood clots and a soft encephaloid or brain-like substance, which oozes through the wound. I find the limb is excavated or honey-combed almost throughout its entire thickness, the cavity extending across the bone into the outer side of the leg. It also extends upward, involving the capsular ligament and the joint. In view of the fact that the disease has gained such a foothold, and that the destruction of tissue has been so great, no operation can prove of any avail for this man except the amputation of his leg at the hip-joint. In this opinion I am sustained by my colleagues, Drs. McCann, Hamilton and King. Even this, I fear, will be but a respite or prolongation of the man's life, but as it is the physician's province to prolong life, we are justified in making the attempt, however desperate may be the chances. The limb being now removed is not sufficient; all of the diseased tissue remaining in the stump must be dissected out, or a speedy return of the disease would result. In deference to the general opinion we will not trust to torsion, in this case, to control the hæmorrhage, but strong catgut ligatures will be used. All of the hæmorrhage must be controlled before the wound is closed, for fear of hæmorrhage into the wound, causing wound tension. A rather large sized drainage-tube will be inserted and the wound will be closed by silver sutures. The usual antiseptic dressings will be applied and the patient will be at once removed to bed. Stimulants, such as brandy, whisky and ammonia, will be given to him, and he will be surrounded by bottles of hot water, in order to assist reaction. If he does well, which we hope that he will, the dressings will not be disturbed for several days, at which time the drainage-tube will be removed.¹

MEDICAL PROGRESS.

WEIL'S DISEASE.—W. BRODOWSKI and T. DUNIN (*Deutsche Archiv für klin. Med.*, Bd., 43, H. 4 u. 5) say that, although there have already been a number of cases of this affection described, its cause and nature are not well understood. The present case, therefore, deserves especial attention, since it is accompanied by the report of the autopsy. The patient, a strongly built and well

nourished man of 36 years, had been attacked about ten days before with severe headache, and had since suffered with repeated chills, with great pain in the abdomen, constipation, and some sweating. When examined, he exhibited some jaundice and swelling of the feet, a few râles in the lungs, especially on the left side, and a temperature of 100.4° F. and pulse of 96. The liver and spleen were decidedly enlarged, the lymphatic glands of the neck, axilla, elbow and groin were enlarged and tender, and the sternum and long bones also somewhat painful on pressure. The urine contained bile and a small amount of albumin, with numerous hyaline tube-casts. The blood contained a somewhat increased number of leucocytes, but was in other respects normal. After being under observation five days the patient died in collapse, having in the meantime suffered from increasing and very intense pain in the region of the liver, more marked cedema and jaundice, and a greater number of râles in the lungs.

The diagnosis had to be made from enteric fever, acute yellow atrophy, continued malarial fever, and leucæmia. The first was excluded by the absence of roseola and intestinal symptoms, and the presence of enlarged liver and lymphatic glands, and of tenderness of the liver. The second was excluded by the slight degree of icterus and the enlargement of the liver; and the third by the symptoms connected with the liver, kidneys, and lymphatic glands. At first the disease was thought possibly to be a case of subacute leucæmia, but this also was excluded by the state of the blood, and the presence of jaundice and albuminuria. The authors accordingly were of the belief that they had to do with a case of Weil's disease; and described it accordingly as *hepatitis parenchymatosa acuta, nephritis acuta, tumor lienalıs acutus, adenitis generalis acuta*.

The principal results of the post-mortem examination were as follows: The lungs were very hyperæmic and cedematous; and in the lower portions there were many thickened portions which felt like spleen, could be easily crushed, and, on section, were of a deep red color. The liver was enlarged and paler than normal. On its surface and section there were numerous irregular spots, the color of yellow clay, which followed the branches of the portal vein. The liver acini were well marked. The spleen was enlarged at least five-fold, dark red, and of almost fluid consistence. The kidneys were twice their natural size, the surface smooth, grey-red, and covered with small white spots. The cortex was twice the natural thickness, and similar white spots were visible. The medullary portion was redder than the cortical, and white spots were visible at the bases of the pyramids. The thoracic and abdominal glands were enlarged, soft, and reddish-grey. The microscopical changes are described in full;

¹ March 6.—This patient lived for three weeks and died suddenly from secondary hæmorrhage. A postmortem examination showed that the carcinoma had extended into the pelvis, and involved the common iliac artery.

the principal ones being as follows : In the thickened portions of the lungs there was an extravasation of blood in the vesicles, and foci of small-celled infiltration in the interstitial tissue, especially along the course of the larger veins. The yellow spots in the liver consisted of a similar cellular infiltration, which was much more abundant in the inter-acinous portion of the connective tissue than in the intra-acinous tissue. The liver cells were in some parts atrophic and compressed, in others swollen. They were cloudy, and many of them tinged with bile. In the kidneys the condition was quite similar; the spots alluded to consisting of cellular infiltration of the interstitial connective tissue, especially in the cortical portion. The epithelial cell were swollen and cloudy. In the spleen there was small hæmorrhagic extravasations, and the small celled infiltration was seen between bundles of connective tissue. The result of a bacteriological examination was practically negative.—*American Journal of the Medical Sciences*, June, 1889.

PULMONARY VENTILATION AND AMPLIFICATION OF THE THORAX UNDER THE INFLUENCE OF GASEOUS INJECTIONS.—BERGEON (*Lyon Méd.*, No. 13, 1889) has again brought forward his "method" under a different theory and for a different purpose. On the ground that carbonic dioxide inserted into the rectum is rapidly absorbed and eliminated by the lungs, and thus *increases the pulmonary ventilation*, he advises this treatment for pulmonary phthisis, reports several cases, and draws conclusions which may be summarized as follows :

1. Gaseous injections furnish a rapid means of increasing the perimeter of a thorax of insufficient size, and this increases the capacity of resistance to the catarrhal affections of the respiratory passages so frequent in those predisposed to pulmonary phthisis.

2. They aid in producing the disappearance of the tubercle bacilli by increasing the vital resistance and the pulmonary ventilation, and by modifying the nidus in a way antagonistic to the development of the microbes.

3. They exert a favorable action even in febrile phthisis; but in order that this action may be salutary and not harmful, it is necessary to comply strictly with the condition that the gas be obtained from a natural mineral water. If an artificial gas is to be associated with this, it is necessary that it be prepared in a condition of absolute purity.—*American Journal of the Medical Sciences*, June, 1889.

THE WALK OF ATAXIC PATIENTS.—DEMANY and QUÉNU have studied the walk of ataxic patients by means of the exact process of photography, and by means of the impressions of the foot upon the soil through a registering dynamometer.

The process is an application of the methods inaugurated by M. Marey for the physiological station. The walk of ataxic patients differs from the normal in characteristic points which photography of the conspicuous parts of the body demonstrates. The bending of the head, the shoulder, the hips, the knee and the ankle obtained photographically, by means of incandescent lamps attached to the joints of patients, are abnormal in a perceptible degree.

The bending of the hip presents an abnormal sinuosity, whilst the foot is lifted. The knee is strongly lifted a little before it is posed, then it is roughly let down simultaneously with the foot, describing at the ankle a sort of circle the last element of which has a retrograde direction. The prints of the registering dynamometer are especially characteristic; instead of presenting two maxima divided by a minimum, they consist of a winding curve ascending gradually into an undulating plateau. In a second type, corresponding to a heavy step of the foot upon the ground, the impression ascends rapidly, but does not remain at its height. The incoördination of the movements of the lower limbs manifests itself chiefly during the period of lifting, in the moment of rest. The leg and thigh extend quickly and simultaneously, thus producing the heavy fall of the heel on the ground.—*La Semaine Médicale*, No. 18, 1889.

TREATMENT OF EMPYEMA BY A VALVULAR TUBE HERMETICALLY SEALED TO THE CHEST.—DR. WM. WILLIAMS, physician to the Royal Southern Hospital, Liverpool, describes in the *British Medical Journal*, of May 18, the principle and mechanism involved in this plan of dealing with empyema. He says :

The principle of the treatment by my valvular tube is the taking away of the atmospheric pressure from the external surface of the lung while the opening in the chest-wall still remains, and so enabling the organ to fulfil its functions and to fill up its side of the chest from the first, without waiting for any falling in of the side to take place; in other words, to cause the lung to expand at the commencement instead of at the end of the treatment.

The method of carrying out this principle is the following : A rubber tube a yard and a half in length, and of a thickness that will admit of its being introduced through a cannula of the ordinary size used to open empyemas, is taken, and one end is introduced into the chest by this means; over the tube, starting from the free end, is next run up an oval, slightly-curved—concave towards the chest—metal plate or shield, three inches by two inches, having a metal tube half an inch long soldered in a hole in its centre, and projecting on the convex side only; through this the drainage tube passes as the shield is run up

to the chest, and they should, of course, fit each other air-tight. Now, between the plate and the chest stiff ointment on dressing, or a layer of soft rubber sheeting, or what not, is placed so as to form an air-tight joint, when the whole is finally firmly strapped down and bandaged. Turning again to the free end of the drainage-tube. We fix on to it by means of a piece of glass tubing a valve that opens outwards, and the contrivance is complete. The valve end of the tube when in use is placed in a bottle containing some antiseptic solution, as the valve acts best in a liquid, and the bottle forms a convenient and cleanly method of dealing with the discharge of pus. Lastly, once or twice each day the valve is removed and the chest washed out by simply elevating and lowering the bottle and changing its contents. It is essential that this should be done often at first, to thin the pus, which is then frequently very thick, presenting while in that state greater difficulties to its expulsion through the valve than when more fluid, and no obstacle should on any account be allowed to cause a postponement of the application of the valve for a single day.

By means of this mechanism the side of the chest acted upon is converted into the cylinder of a pump, of which the diaphragm forms the piston, having two exit openings, trachea and rubber tube, but only one inlet opening, trachea alone; therefore, each time the diaphragm ascends, the contents of the lung and also that of the pleural cavity are expelled; but each time the diaphragm descends only air into the lung can enter the chest; so each quantity of pus that is driven out through the tube during expiration is replaced at the next inspiration by so much re-expanded lung. By a repetition of this action the pleural cavity is ultimately pumped dry, and so the lung is made to reoccupy it; the action is, in fact, that of a continuous aspirator, and that it actually does take place is, I think, without doubt.

ON THE EFFECT OF CORONILLIN UPON THE HEART.—Coronillin acts electively upon the heart. In doses of 0.005 gr. it acts much like digitalis upon the heart of frogs. In mammiferous animals (dogs) the heart's action is first accelerated, afterwards much slackened. But this phase of slackening is completely suppressed by previous section of the two pneumogastries, or the medulla, or by atropinization. In these conditions only an increase of the intra-arterial pressure is observed consecutive upon every injection of 0.0005, or 0.001 gr., after which always a marked and persistent diminution follows. The animal dies from stoppage of the heart. But at the last period of intoxication the cardiac contractions become unable to maintain the intra-arterial pressure, so that this sinks down to nothing before the heart is

completely stopped. M. Gley, who made these experiments, together with M. Schlagdenhauffen, of Nancy, found also that the nerves of the heart presented different grades of irritability under the influence of coronillin.—*La Semaine Médicale*, No. 17, 1889.

THE TREATMENT OF DIARRHŒA IN PHTHISIS.—DR. POLYÁK, of Görbersdorf, gives in the *Orvosi Hetilap*, the results of some trials he has made of two recently suggested remedies in the diarrhœa of phthisis—viz., silicate of magnesia in the form of talc, which has been recommended by Debove, and lactic acid recommended by Drs. Sézary and Aune. About 8 ounces of talc were well shaken up in a pint of milk, and this, or even a larger quantity was given daily. As a rule it arrested the diarrhœa after having been used for a couple of days, but if it was left off the diarrhœa returned. It was found, however, that patients liked the milk mixed with talc even better than ordinary milk, but it could not be taken for more than six or seven days, as after that time complaint was made of a troublesome feeling of oppression in the stomach and bowels. Dr. Polyák thinks it quite impossible that long-continued use of talc can heal intestinal ulcers. Lactic acid proved in his hands a much more satisfactory remedy. The initial dose employed was 30 grains per diem in four ounces of water; this was increased subsequently, but not more than 75 grains per diem were given. On the third day the diarrhœa and pain were generally arrested, and during the next day or two the stools assumed their ordinary character. It was found advisable to continue to give small doses for some time longer. The patients bore the treatment well; it produced no diminution of appetite, and unless continued for a long time, gave rise to no disagreeable symptoms. Dr. Polyák thinks it possible that even ulcers of the intestines may be healed by this means.—*Lancet*, May 18, 1889.

CONGENITAL ABSENCE OF FIBULÆ.—MR. WM. THOMAS, at the March meeting of the Midland Medical Society, exhibited a child at 4, in whom there was congenital absence of both fibulæ and corresponding parts of feet—viz., the outer two metatarsal bones and phalanges. The feet were in a condition of rigid talipes valgus. He intended to divide the tendo Achillis, and by a specially constructed apparatus to supply the function of the absent fibula.—*Lancet*, May 4, 1889.

FROMENTINE.—DR. DUJARDIN-BEAUMETZ has brought to the notice of the Paris Academy of Medicine a new alimentary substance which he names "fromentine." It contains three times more nitrogenous substance than meal, and a large proportion of sugar. It is obtained from wheat.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dugglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, JUNE 29, 1889.

THE TWELFTH VOLUME COMPLETED.

With this issue the twelfth volume of THE JOURNAL will be completed. For thirty-four years the "Transactions of the American Medical Association" had been compiled and published annually in as many single volumes. The delay incident to the preparation of such a work rendered it necessary often to defer its publication, until nearly the close of the current year. To obviate this delay, as far as possible, it was determined after careful consideration, to issue the proceedings of the Association, with its papers and discussions, in the form of a weekly journal, to which should be added such other original matter, together with notes of Medical Progress, Editorials, Foreign and Domestic Correspondence, Proceedings of Medical Societies, Reviews of Books, Editorial Notes and Medical Miscellanies, such as should make it in every respect a first-class medical magazine. Each member of the American Medical Association is entitled to THE JOURNAL by reason of the payment of his annual dues, without further cost. Thus, there was an assured subscription list as large as the membership of the Association. The advertising public was quick to perceive the value of THE JOURNAL as a medium of communication with a very large number of the most prominent physicians in the country, and the revenue from this source, in addition to the membership fees, has enabled the Trustees to present to its readers a weekly journal, each issue, as now enlarged, containing thirty-six pages of double column, solid reading matter.

Two volumes are published annually. The first commencing with the first day of July, the second with the first day of January. At the close of the sixth year THE JOURNAL now completes its twelfth volume, and enters upon a new year entirely free from debt, with every prospect of abundant success.

Ample provision is made for editorial work, a good list of both Foreign and Domestic correspondents has been secured. It has always at hand an abundant supply of original matter, and commands for publication the proceedings of as many of the leading medical societies of the country as its space will permit.

It is the purpose of the Trustees to make it, in every respect, thoroughly representative, as a National Journal. In no sense will it be partisan or sectional. It invites to its columns the discussion of the living issues of the day, which have for their object the promotion of medical science and the advancement of the healing art. It therefore commends itself strongly to the patronage of medical men who are not members of the Association as a journal replete with original research, and with the expression of the latest thought of many of the best minds in our country.

As an advertising medium it is unnecessary to speak. Experience in the past indicates that its value is fully appreciated.

The number of papers presented, and their authorship, give promise that the Annual Meeting held at Newport during the past week has afforded material for the thirteenth volume, which will render it more valuable, than any which have preceded. *It is a good time to subscribe for THE JOURNAL.*

THE PREVENTION OF PUERPERAL FEVER.

Since the "germ theory" came to be so largely accepted by the profession as an established fact, the study of the septic condition known as "puerperal fever" has been greatly simplified, and its prevention has been made more than possible. Fortunately, this disease has been growing more and more rare during the last quarter of a century, and especially since the principles of Listerism have become firmly established in the minds of the profession. So-called epidemics of the disease have been rare, if indeed not entirely wanting, throughout the entire Mississippi Valley, and

where any number of cases have occurred in close proximity of time and locality, a common medium of infection has been easily made apparent by careful inquiry and investigation. Atmospheric conditions are no longer considered to be important factors in the production of puerperal fever, further than that they at times conspire to lower the standard of vital activity in the economy of the subject, and so prepare a suitable soil for the reception of any infective plant that may be introduced from whatever source. The puerperal woman is frequently the subject of various febrile conditions accompanied by chills and other alarming symptoms, not in any way due to septic influences in the true sense of that term, and which promptly yield to the appropriate therapy, and which are not to be confounded with the phenomena known as puerperal fever proper.

Puerperal fever or puerperal septicaemia, however, does occur, and occurs too often, as it is a settled fact, in large measure, that this is a preventable disease; that the immediate environments of the lying-in woman are the sources from which her dangers arise, and that directly in proportion as these dangers are met and removed, is her immunity from the disease assured.

The large amount of decaying tissue, the denuded condition of the entire intra-uterine surface, and the gaping mouths of its sinuses, incident to the puerperal state, all conspire to make this an inviting field for the planting and culture of infective germs. When once introduced into this extremely fertile soil and well established throughout the field, the progress of the disease is readily understood. The two processes by which the work of involution is accomplished, that is, sloughing and absorption, must occur in close proximity. The two flowing streams must originate at distances from each other unappreciable, and it is not difficult to understand how the infective germ finds its way into the general circulatory system. This seems plainly to be the story of the disease. The route by which the disease-producing germ may have reached the cavity of the uterus, is doubtless by way of the vaginal tract, and hence is suggestive of preventive measures to be employed. There seems at present to be no doubt entertained as to the practicability of preventing this formidable disease, which a few years ago left so many homes wifeless and motherless. The means to be employed are simple enough, but ex-

acting in every detail. Absolute and uncompromising antisepsis is the only safeguard of the lying-in woman, and the accoucheur of to-day, with present information on the subject at hand, is derelict of duty who leaves any one of the many details of antisepsis unobserved, and it may safely be predicted that, in the near future, he will not have been sustained by the profession who may have inadvertently neglected the recognized precautions to the injury of his patient.

EDITORIAL NOTES.

HOME.

THE JOHNSTOWN SUFFERERS.—The *Maryland Medical Journal* has opened a subscription list for the relief of those physicians and their families who are sufferers from the flood. Up to the 15th inst. \$181.00 had been received.

WE regret to learn of the continued illness of Dr. Oscar J. Coskery, of Baltimore, who has been removed to St. Joseph Hospital.

DR. GEORGE H. MAKUEN, of the Staff of Cooper Hospital, Camden, N. J., has been appointed assistant demonstrator of anatomy in the Jefferson Medical College.

THE AMERICAN INTERNATIONAL CONGRESS OF MEDICAL JURISPRUDENCE held a convention in New York from June 4 to 7. Delegates were present from England, Canada, Russia, Italy, and from nearly every State in the Union. A full report of the proceedings will be found in *The Medical-Legal Journal* for July.

PROF. DAVID SWING, of Chicago, has been elected a trustee of the Northwestern University.

A NEW HOSPITAL.—A public hospital will shortly be erected at Memphis, Tenn., under the auspices of St. Mary's Catholic Church. It will be entirely non-sectarian, and nursing and attendance will be gratuitous to all patients unable to pay.

A TEST FOR ANTIPYRIN.—The *Pharmaceutical Journal* gives the following test for antipyrin: Place in a test-tube a few grains of potassium nitrate, add a little water and then excess of strong sulphuric acid, and fill up the tube with the suspected liquid. A green coloration is immediately produced if antipyrin be present. This test is delicate and reliable and has the ad-

vantage of being specifically characteristic of antipyrin.

PROF. R. BARTHOLOW recommends bromide of lithium to be about the best remedy for muscular rheumatism.

THE people of New Orleans are determined to do away with the system of surface drainage so long in use. They are agitating for underground drainage.

THE Senate of Massachusetts threw out the proposed medical bill on a vote of five to eighteen after it had passed the lower House.

THE BROOKLYN EYE AND EAR HOSPITAL is the recipient of \$5,000 under the will of the late Hon. S. B. Chittenden.

A HOSPITAL FOR DARTMOUTH.—The *New York Times* says, that Mr. Hiram Hitchcock, of the Fifth Avenue Hotel, has given to Dartmouth College a hospital which is to be attached to the medical school of that institution.

THE NEW EDITOR OF THE "MEDICAL NEWS." The proprietors of the *Medical News*, of Philadelphia, have secured the services of Dr. Hobart A. Hare, as editor. Dr. Hare, in conjunction with Dr. Edward Martin, has been awarded the Warner Prize of \$500, offered by the Massachusetts General Hospital, for the best essay on the treatment of persons apparently dead from failure of respiration.

THE NEWPORT MEETING.—The President's Address and a full report of the general sessions will appear in our next issue, which will be mailed early in the coming week. There were about three hundred papers read in the various Sections, which will be published in THE JOURNAL. Now is the time to subscribe, or to become a member by application.

DR. F. H. REHWINKLE, of Chillicothe, O., died on the 7th inst. from the effects of a stroke of paralysis. An extended notice will appear under the head of "Necrology."

DR. S. EDWIN SOLLY, of Colorado Springs, Colo., paid us a visit on his way to the meetings of the American Climatological and American Medical Associations. After the meeting at Newport Dr. Solly will sail for Europe.

FOREIGN.

DANGERS OF FOREIGN TRAVEL.—We learn

through the *British Medical Journal*, that Sir Edward Watkin is energetically calling attention to the lamentable sanitary defects in one of the great hotels at Cannes, to which he has attributed the recent illness of several members of his family. A thorough inspection of foreign hotels is advocated. It is a fact that on both Continents the same cause of complaint exists at health resorts. The sanitary laws should be enforced, and if necessary, special legislation obtained to make the greed of hotel proprietors subservient to the public welfare.

A BRAVE SURGEON.—Mr. C. D'Alton, surgeon of the "Cotopaxi" of the Pacific steamship line, distinguished himself recently by his courageous conduct in rescuing two passengers. The vessel struck a rock in the Straits of Magellan and foundered. During the eight minutes of awful suspense Mr. D'Alton noticed that two passengers were paralyzed and unable to help themselves, and acting with promptness and presence of mind he rescued them, even procuring bedding from his own cabin for the use of the worst of the two cases.

LEPROSY IN ENGLAND.—The Royal College of Physicians are urging the British Government to renew the investigation of the question of the contagion of leprosy. The disease is believed to be contagious and not hereditary.

PAINLESS EXTRACTION OF TEETH.—Drs. Henoque and Fredel, in a communication made to the Biological Society of Paris, state that the extraction of a tooth may be rendered painless by spraying the neighborhood of the external ear with ether. The anesthesia of the trigeminal so produced extends to the dental nerves, and thus renders the production of general anesthesia needless.

DR. JOHN GUITERAS, of the U. S. Marine-Hospital Service, is authority for the statement that the City of Havana has had an annual epidemic of yellow fever for over one hundred years. July, August and September are the fatal months.

DR. JOHN FREIND.—The current number of *The Asclepiad* contains a well-executed portrait of the celebrated medical historian, John Freind. Accompanying it is an interesting sketch of his life as student, practitioner, politician and historian.

SOCIETY PROCEEDINGS.

Medical Society of the District of Columbia.

Stated Meeting, February 6, 1889.

DR. C. H. A. KLEINSCHMIDT IN THE CHAIR.

DR. J. TABER JOHNSON presented a specimen and history of

SUPRA-VAGINAL HYSTERECTOMY FOR A LARGE UTERINE FIBROID.

I first saw this patient with Dr. Sellhausen. She had a large fibroid tumor of the uterus which she had carried about for fifteen years, but was now confined to her room on account of constant hæmorrhages. She was a spinster, æt. 53; a German who could speak no English, and earned her living as a dressmaker at the rate of 75 cents a day. Upon vaginal examination a polypus was discovered protruding from the external os about the size and length of one's thumb. It was thought, that as hæmorrhages had not in the past been a feature of her case, that this polypus might be the cause of her loss of blood, and its removal was proposed and agreed to at once. Miss H. engaged a private room in Providence Hospital for this purpose. She being an aged virgin it became necessary to administer ether in order to insert a speculum. The removal of this growth did no good. The bleeding continued, and, as the patient was unable to continue her work, and being without means to obtain a living she requested that the tumor itself be removed, if possible. After consultation with her friends and physician it was determined to make the effort, as the poor woman had no other prospect in life than the charity ward of a hospital or the poor-house.

Supra-vaginal hysterectomy was therefore performed. The broad ligaments were tied off on each side, and Keith's clamp applied at the head of the internal os, and the tumor cut away. The pedicle was treated as recommended by Keith and Bantock—a drainage tube put in and the wound closed up to and around the stump which was sewed to the peritoneum. There was no shock and the patient did very well for the next twenty-four hours. She was cheerful and bright, and had very little pain. She passed a normal quantity of urine. The second night after the operation, her temperature jumped up without warning to 104°, and then as rapidly fell, and she went into a collapse from which she could not be aroused. Her temperature the next morning was 95°, and she died at noon on the third day. There was no hæmorrhage and only a very slight peritonitis about the edges of the wound. She seemed to die of what is called secondary shock, or perhaps from the shock of a commencing peritonitis.

She may have been too weak to stand the operation, but Keith, in his little work on "Thirty-eight Cases of Supra-vaginal Hysterectomy," states that some of his most anæmic cases did the best, and strong hopes were entertained of the recovery of this patient. Soft friable patches were found on the inside of the uterus which were probably the seat and cause of her hæmorrhages, and which perhaps might have been removed with temporary benefit with the curette. Hæmorrhages are frequently arrested when this condition is present both with the curette and with cauterizing action of the electrical current. The size and friability of these masses gave rise to the suspicion of malignancy, and I requested Dr. Lamb to examine and report on this point. Perhaps the sudden collapse of the patient was, in a measure, due to the undermining of her constitution by the cancerous process added to her loss of blood.

DR. SWAN M. BURNETT presented a specimen and history of

SARCOMA OF THE CHOROID.

I saw the patient from whom this eye was removed for the first time just two months prior to the enucleation. At that time he was practically blind in that eye (the left), and had been for some time—as to how long he was very uncertain. He was of the opinion, however, that the sight had been failing for some years. There was a total detachment of the retina; tension about normal; probably some perception of light at the lower inner quadrant of the visual field; pupil reacted only concentrically. As the other eye was emmetropic, and there was no history of trauma, and the patient was near 60 years old, my suspicions as to an intra-ocular growth was almost a conviction. I advised care in the use of the eyes, and ordered him to report from time to time, and at once upon the appearance of redness or pain, and assuring him, without telling him of my suspicions, that it was the kind of an eye that someday would almost surely require surgical interference. Two weeks ago he reported with some pericorneal injection, and a complaint of severe orbital pain setting in suddenly. There was plus tension; the cornea was hazy with the epithelium raised in places; pupil not dilated. Under cocaine, hot applications and rest, the more acute symptoms subsided. I warned him that on a second outbreak of severe pain operative interference would be necessary at once. I went to New York, hearing from him every day, and finally at the end of the second week since first seeing him I was telegraphed for. I found the usual feature of severe cyclitis, bordering on to panophthalmitis—7+2. Enucleation, under ether, was done at once, the operation being perfectly smooth.

On section of the enucleated eye the following appearances were found:—total detachment of

the retina, a tumor on the inner wall reaching from the optic nerve entrance to beyond the equator, and filling about one-third of the cavity of the globe. The sclera was not ruptured, and the cut surface of the optic nerve seemed, on microscopical inspection, to be healthy.

The tumor shows minute dots of pigmentation, and I am quite sure it will exhibit under the microscope the characters of a *melanotic sarcoma of the choroid*. Intra-ocular tumors are of two varieties—sarcoma of the choroid, rarely or never met with in persons under 12 years of age, and glioma of the retina, never found in those over that age. The important lesson to be learned from this case is, that when there is a detachment of the retina in a person over 50 not affected with myopia, and with no history of trauma, to suspect an intra-ocular tumor, and if the vision is lost, to advise an enucleation at once.

DR. T. C. SMITH asked Dr. Burnett what would be the probability of systemic infection in his case, and also the proportion of cases subsequently infected.

DR. BURNETT: In sarcoma of the choroid where the optic nerve is not involved there is little danger of its involving the orbit, or causing systemic infection. If a microscopic examination showed that the optic nerve was diseased in this case then he would fear a return of the disease in the orbit. In glioma there is generally systemic infection.

DR. BERMANN: Did Dr. Burnett obtain a family history of such tumors?

DR. BURNETT: He had learned that the patient had had two epitheliomatous warts of the cheek and lip, which had been removed by the late Dr. A. Y. P. Garnett, and they had not returned. This was the only history bearing upon malignant growths in this family.

DR. GEORGE WOODRUFF JOHNSON reported the following:

1. SUPERNUMERARY BREAST. 2. FIBROID OF THE VULVA. 3. SARCOMA OF THE FEMALE URETHRA. 4. MELANOTIC SARCOMA OF THE CERVIX UTERI. 5. FIBROUS TUMOR OF THE CERVIX UTERI.

DR. THOMPSON: Dr. G. W. Johnston has spoken of the rarity of pediculated fibroids, but was it not much rarer to find sarcomata pediculated?

DR. G. W. JOHNSTON thought his specimen was a sarcomatous degeneration of a fibroid polypus. As was well known sarcoma could occur in the uterus either as a diffuse degeneration of its lining membrane, or as the so-called fibro sarcoma. In the latter variety the tumor is sometimes intramural, sometimes subperitoneal or submucous, and either of the last two forms may become pediculated.

DR. THOMPSON had never seen a pediculated sarcomatous tumor. Dr. Burnett's case has not been definitely settled. If he should operate upon a tumor which he knew to be sarcomatous in the region of Burnett's he would have the gravest apprehensions as to its return. Sarcomata are often locally as malignant as carcinomata. He had recently operated for sarcoma of the testicle, removing everything to the abdominal ring, but the growth returned and killed the patient. He had operated on others and the sarcomata returned. The tendency of sarcoma is to return; it is different with fibromata.

He had sometime ago removed a well-defined tumor from below the angle of the scapula; the wound healed by first intention; it soon returned; he operated again, cutting the muscle from the ribs; and the wound healed again. In five or six months the tumor had grown to be as large as one's head. He told him to go to the hospital, but he declined. Sometime after that he saw him sitting in front of his house and stopped to inquire about the tumor. He learned that he had been under another's treatment and said he was well. The patient described the tumor as breaking down like clots. He examined him and he was well. Three months after he again examined him, and to his surprise he found him well both locally and constitutionally. He thought this one of the most remarkable cases he had ever seen. In carcinoma such a cure would have been impossible. Sarcomata remain locally malignant for a long time.

He gave the details of another case of enlarged scrotum into which hæmorrhage had taken place, and it had swelled to an enormous size while the man was sitting quietly at his desk. He operated and removed large clots and broken-down tissues which gave it the appearance of malignancy; he removed the entire scrotum of the side upon which the tumor was situated. He had had a number of successful operations upon sarcomatous testicles.

DR. LAMB: There was probably a profuse hæmorrhage in the first case, forming clots which subsequently broke down.

DR. THOMPSON thought it was a solid tumor which had ulcerated. He had removed a cystic tumor from the outer side of the arm of a young man, which looked very black at different points. He thought he took out all of the diseased tissue, but it returned in about six weeks, was very much harder and did not fluctuate. He operated a second time and cured the patient. Some sarcomata do not return when once thoroughly removed.

DR. BERMANN was interested in the case reported as polypoid sarcoma of the urethra. He was dubious of the right of calling it a sarcoma. He has frequently removed polypi from the nose and found that when they had existed for a long

time that they resembled sarcomata. If this is true why should we call polypi of the urethra malignant.

DR. LAMB: In the large tumor on the side and ribs, mentioned by Dr. Thompson, the blood supply was probably cut off, fatty degeneration took place, and the tumor disappeared independent of medicinal treatment.

DR. J. TABER JOHNSON asked Dr. G. W. Johnston how long it had been since he removed the sarcomatous growths and if any had returned. Dr. Johnston had assisted him in removing a sarcoma situated between the vagina and rectum. A microscopical examination proved it to be a melanotic sarcoma of the worst type. As yet there have not been any symptoms of reappearance, but he was not certain that time enough had elapsed to see whether it would return.

DR. G. W. JOHNSTON had seen the urethral case one and a half months after its removal. The wall and tissues were hard and tough, and the urethra had regained but little of its elasticity. His treatment after the removal of the growth was for the purpose of making the wall of the urethra contract. The microscopic diagnosis had been made some time after the removal of the tumor and since then he had not seen this patient. He would not stand sponsor for the diagnosis in these two cases. He did not even suspect malignancy until after he had received the report of Dr. Gray.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

New York County Medical Association; Dr. T. H. Manley on the Operation for Strangulated Hernia known as the McBurney Method—Appointment of a Committee to confer with the New York Board of Health with a view to securing a more perfect Registration of Births.

At the May meeting of the New York County Medical Association Dr. T. H. Manley read a paper on the *Operation for Strangulated Hernia* by the method which Dr. McBurney recently described before the Academy of Medicine, and in it gave a report of three interesting cases recently operated on by himself at the Harlem Hospital. They were all of indirect inguinal hernia, and the operation was performed with a view not only to relieving the constriction, but also at the same time permanently curing the trouble. In devising this procedure, which enabled the surgeon to secure both these ends by means comparatively simple and infinitely safer than any others yet proposed, he thought there could be no doubt that Dr. McBurney had achieved one of the greatest triumphs of American surgery.

The cardinal points of this operation, which he said were for the most part decidedly original and which, if well understood and skilfully applied, would almost invariably lead to successful results, are, it will be remembered: 1, an open wound—hence no septic infection or purulent infiltration; 2, the incision of the sac; 3, the suturing of the cutaneous and aponeurotic edges of the wound together; and 4, the closing in of the breach by means of cicatricial tissue. The difference in the character of the three cases of Dr. Manley rendered necessary some modifications in their management; but in all there were followed out these fundamental points laid down by Dr. McBurney, whose operation was recommended for every variety of abdominal protrusion.

The first case was that of a male 45 years of age whose hernia, on the left side, had existed as long as he could remember. From time to time the protrusion would disappear spontaneously, though he always wore a truss, and up to the day before he entered the hospital the patient had not noticed it for more than four months. On this day, after unusual straining at stool, the tumor reappeared, larger than ever and unusually tender to the touch. The man himself and his family physician both having failed in reducing it, he was sent to the hospital. At this time there were no signs of strangulation and, as his condition was very good, he refused to submit to an operation, which was strongly urged. Four days after the reappearance of the hernia well-marked symptoms of strangulation showed themselves.

The patient was now eager for the operation and, an anæsthetic having been given, the skin was quickly incised by one stroke of the scalpel carried from a point just over the intestinal opening of the inguinal canal to an inch below the external ring, and then the coverings were divided until the sac was reached; the region of the neck being first sought and the body cut down on later. The sac was found to be an old one and bound down by very firm adhesions, which were separated only with the greatest difficulty. Within the sac was a knuckle of intestine, with a large quantity of effused serum. In performing this operation it is inculcated to leave the spermatic cord alone; but in this case there was no spermatic cord, either within or without the sac. When the canal was opened the cause of all the trouble was found, viz.: an undescended testicle, which was normal in shape, but not much larger than a kidney bean. By making considerable traction it could be readily brought out of the canal, and Dr. Manley considered the fact that the inguinal opening was patent throughout attributable to the defective development; the testicle sometimes slipping down through the ring, and then returning again. This condition had naturally kept the patient in a constant state of danger, and the displaced testicle was also the

cause of the discomfort which he said he had habitually experienced when wearing a truss. After completely opening the canal and removing the testicle, traction was made, and the whole of the protruding portion of the serous sac ligated and cut off. The cutaneous edges were drawn down to the divided edges of the canal, and six sutures put in on each side: after which the open wound was packed with iodoform gauze and the usual antiseptic dressings applied. After the operation the patient never rallied, and death ensued four hours after its completion. This man's life, Dr. Manley said, should have been saved, but it was lost through his refusal to submit to an early operation; the delay resulting in septic infection of the peritoneum and general exhaustion of the system.

The second case was in a male, 29 years of age, who had worn a truss for many years, but discarded it about a year before, when his rupture disappeared. It suddenly returned one day while he was making severe exertion, and several physicians having failed to reduce it, he came to the hospital. As in the preceding case, an immediate operation was advised, but the patient refused, and the tumor, which was very small, remained unreduced in spite of all treatment. The next day there was a marked change for the worse, and locally there was found marked fulness along the cord in the inguinal canal, while the scrotum was distended with an enormous hydrocele and the hernia itself had increased to more than five times its original size. In addition, there was well-marked peritonitis in the region of the sac, with a tendency to rapidly become general, and altogether, septic infection was evidently in full progress.

Under such circumstances the success of any cutting procedure was very doubtful, but an operation was now, of course, the only resort. The great advantage of the McBurney method in cases like this, Dr. Manley said, was that we had a large open wound for free drainage, and an opportunity to remove as occasion required any diseased or contaminated tissue met with. In this case the hernia had no sac. As in the preceding instance, there was an old congenital impediment (though here the testis had descended), and the spermatic cord dangled in the centre of a large pouch. Hence, to carry out the operation according to the method adopted it was necessary either to sacrifice the testicle or make an artificial investment for it. As the latter would render the patient liable to another hernia at an early date; and, moreover, as it was found that the *vas deferens* was reduced to a mere thread and the testis was very imperfectly developed, and therefore probably useless functionally, the organ was removed. In order to secure a continuous sac the unclosed tunica vaginalis had to be dissected off all the way up to its origin at the internal ring. The protrusion

consisted of a small knuckle of intestine with a large mass of discolored and partly gangrenous omentum. The latter was drawn forward until healthy tissue was reached, when it was ligated and cut off; after which the sac was cut off and the wound treated in the usual way. Though Dr. McBurney laid stress upon the importance of keeping the patient in bed for six weeks after the operation, this one (whom Dr. Manley exhibited to the Association), could not be persuaded to keep quiet so long, and left the hospital, perfectly well, on the twenty-ninth day.

The third case was that of a woman 51 years of age. The hernia had existed for fifteen years, and ten days before her admission to the hospital she found that it was impossible to replace it as usual. She also became obstinately constipated, and numerous enemata had no effect in relieving the bowels. On the night of the tenth day symptoms of strangulation set in, and her physician, who had previously exhausted every means to reduce the hernia, advised her to enter the hospital. She was admitted at midnight, and Dr. Manley saw her one hour afterwards, when her condition was exceedingly serious, notwithstanding the fact that, from the moment of her entrance, stimulants had been freely administered and artificial heat assiduously applied.

The operation was commenced as promptly as possible and, on account of the extreme exhaustion of the patient, special effort was made to render it as brief as consistent with thoroughness. When the peritoneum was reached it was found that it had formed a pouch which was firmly adherent to the surrounding parts and, from the thickness and toughness of its walls, undoubtedly an old one. The sac, close to the inner side of which lay the round ligament, was divided in a longitudinal direction, when it was found that the greater part of its contents consisted of omentum which, towards the neck, was very firmly adherent to its serous covering. Immediately under the protruding part was discovered a small knuckle of intestine, of a port wine color, with its peritoneal investment, which had a peculiar granular feel. After the sac had been torn from all its connections with adjacent parts it was opened in the lower portion, which permitted the drawing down of the omentum to a slight extent. This having been done, it was ligated in mass, and the stump returned to the peritoneal cavity. In this case, as in the others, the inguinal canal was opened throughout its whole length.

The last steps of the operation, the sewing together of the skin and aponeurotic structures, and the packing of the wound, presented unusual difficulties in this instance, on account of the extreme amount of adipose tissue in the abdominal walls; but by somewhat modifying the *technique* of the operation these were overcome. Though the patient was quite weak for a few days, all her

dangerous symptoms disappeared with the operation; she made a rapid and satisfactory recovery.

Until the time of the McBurney method, which offered additional advantages that no other possessed, Dr. Manley went on to say, the operation for strangulated hernia was attended with a fearful mortality; Bryant putting it at 50 per cent. in the hands of the best operators. By a strange coincidence there were admitted to the Harlem Hospital during the first week in July, 1888, three women suffering from strangulated hernia. The first was a healthy, muscular individual, 29 years of age, and the second was 50 and, though of a spare figure, also in good general health; while the third was 65 years old and greatly emaciated and reduced in strength. The most persistent efforts at reduction by taxis failed, and all were operated on within twenty-four hours after the latter were abandoned. The operation was simple, as the only aim was to release the constriction and return the protrusion; but two of the patients died within forty-eight hours after the operation, and the one who recovered, strange to say, was the feeble old woman of 65.

Dr. Manley said that though there might be a diversity of opinion as to the propriety of doing any operation in the case of an individual with a hernia that could be comfortably borne with the aid of an easy truss, or in the case of very young children, he could hardly conceive of any objection when strangulation was present against a procedure which, while it obviated the greatest dangers of this condition, afforded, in addition, a reasonable prospect of a permanent cure and the freeing of the patient from the unceasing burden of a truss. There were two great sources of danger encountered in every case of strangulated hernia operated on which the McBurney method always eliminated, viz.: peritonitis from septic infection, and hæmorrhage. As far as immediate danger to life was concerned, all other dangers, bleeding included, sink into insignificance in comparison with the former of these.

If there was localized contamination a free opening could be made, and the cavity of the peritoneum boldly entered. If any of the extruded parts were undergoing putrefactive changes it was removed. If there was reason to suspect that the serum of the peritoneum had become infected an opening might be made by the exposure of the ring, or perhaps the crural arch, and if this were not free enough it could readily be enlarged by an incision into the fibrous tissues, and the whole region flushed with some efficient antiseptic wash; while, to be more certain that no pent-up decomposing material remained, a drainage tube could be introduced. To the objection that the free use of the scalpel in dividing the strong bands of aponeurotic structure would tend to weaken the abdominal walls, it could be answered that we would resort to this only in a very severe

case where general contamination was feared. Besides, immediately after the parts were well washed out the line of incision would be solidly sutured.

As to hæmorrhage, this method marked a new era in dealing with inguinal bleeding. It put an end to the blind groping with a stub or blunt-pointed blade for a part which should be recognized by the touch only. Under the old plan of procedure the one great thing which the surgeon feared in dividing the constriction was hæmorrhage; and hence very great stress was laid on the importance of keeping well in mind the bearings of the blood-vessels, for, unfortunately for the patient, if a deep vessel happened to be cut it would scarcely be known until after he was dead. In addition, there was such an exaggerated dread of disturbing the peritoneum that it would be only a very bold operator who would cut down for the divided ends of the wounded vessel. But, with a free open wound, with its edges well separated by retractors and every part well exposed to view, the chances of hæmorrhage were reduced to the minimum, and if it happened that a vessel pursuing an anomalous course came in the way of the scalpel, it would occasion no alarm whatever, since the point of injury would be in full view and the bleeding could readily be controlled by the clamp forceps. The importance of avoiding hæmorrhage was still more appreciated when it was remembered that hæmorrhage, independent of the amount of blood lost, may become a source of danger by exciting inflammation and possibly spreading infection. It was well known that the presence of even a very small quantity of blood would often interfere with primary union of the wound, and in this operation the tissues were not permanently brought into apposition until every vestige of bleeding had ceased.

Having dwelt for some time on the anatomical arrangement of the structures in the inguinal region in his three cases, Dr. Manley went on to say that from his clinical experience and from a most careful and extended series of investigations on the dead body, in the male and female, adult and child, he was firmly convinced that abdominal hernia in its various forms, and especially the indirect inguinal variety, is nearly always attributable to defective development at birth, or to causes acting immediately after it. He referred particularly to his observations upon infants and said he was persuaded, furthermore, that arrest of the descent of the testicle is responsible for the vast majority of hernias in the male.

In the treatment of strangulated hernia by the McBurney method, he continued, among the questions which arose for consideration were the following:

1. How soon should an operation be performed after the hernial protrusion is found to resist taxis?

2. What are the circumstances which call for a modification of the *technique* of the operation?

3. What are the dangers, immediate and remote, in the operation, and how can they be obviated?

4. What class of cases should be rejected?

The first question was more important than all the others, and upon its decision the success of the operation would in a large measure depend. Dr. Manley recommended that whenever a case of hernia which cannot readily be reduced is met with an immediate operation should be advised, provided the facilities for it and for carrying out the most rigid antiseptic treatment of the wound are at hand. Under such circumstances the patient is not worn out with agonizing pain and exhausting vomiting, but is in good condition and almost certain to make a rapid and permanent recovery. What could be promised now (and this constituted one of the principal indications for an early operation), was something which had been hitherto unknown, viz., a complete cure of the hernia. If the patient was in a vigorous condition, but afraid of general anesthetics, a few cocaine injections would suffice to blunt the pain occasioned by the cutting. As the longer the delay the greater was the danger and the smaller the prospect of success, promptness in operating was of the greatest possible importance.

In answer to the second question he stated that the wound made through the skin, fascia and fat must be dealt with somewhat differently in fat and lean subjects, and also with reference to the kind of hernia present and the condition of the tissues, whether healthy or not. In thin individuals little difficulty would be met with in suturing the skin to the conjoined tendon and to the fascia transversalis in oblique inguinal hernia; but in the very fat he believed it was sometimes better to omit this part of the procedure. In his opinion a case would do equally well if, after packing the wound with gauze, the edges were brought towards each other by broad strips of strong adhesive plaster. Of course, if in any case infection were suspected at the site of incision, the wound would have to be made somewhat larger, so as to provide for free irrigation and drainage. A hernia other than the indirect oblique would not require so free an incision. In making the incision the operator should be guided by a single purpose, viz.: to make it large enough to enable him to deal with the deeper structures safely and speedily. In patients suffering from great exhaustion he believed the surgeon should proceed with all possible haste compatible with thoroughness, and he said he could not doubt that prolonged anesthesia was responsible for the loss of many lives. If, on exposing the bowel, there were found positive evidences of gangrene, the result of too long delay, enterectomy was called for; after which the remaining healthy por-

tion of the gut should be returned, and the operation completed in the same manner as if this pathological change had not been encountered.

In a hernia not of congenital origin, Dr. Manley went on to say, the management of the sac was a simple matter; but when its external surface was found to be firmly attached by old and strong bands of connective tissue, it was necessary to carefully and completely detach these before we could be quite certain that we had reached the free floating covering of peritoneal tissue which must be shut off by a ligature, applied high up, before the division of the sac. With recent protrusions accompanied by inflammatory exudations of lymph it was very easy to separate the adhesions; but in irreducible and incarcerated hernias, and those of congenital rarity, the most cautious and tedious dissection was often required, in order not to injure the parts. To an operator familiar with the anatomy of the region and with the tissues met with such adhesions were, however, objectionable only because they prolonged the operation. In every instance where on cutting down upon a hernia it was found to be one dependent on defective development or misplacement of the testes, and likely to occur again in consequence of this impediment, he thought the surgeon should not hesitate to castrate. If the testicle had been an active factor in the production of the hernia it was in his experience pretty sure to be feeble in function; but even if this were not the case the man would still possess full virile power with the other one remaining. With this impediment removed, and the spermatic cord out of the way, we could solidly seal the whole chasm in the abdominal wall, and thus obviate the risk of leaving what might later possibly lead to a repetition of the same trouble.

In the inguinal region there were considerable anatomical and histological differences between the male and the female. In woman the skin was thin, and if they had given birth to many children it was apt to be greatly wrinkled, atrophied, and destitute of strength or elasticity. In those past middle life, too, there was often a large deposit of fat, which, while it did not interfere materially with completing the toilet of the wound, did most decidedly retard the healing process. In such cases it was imperative that the union of the wound should begin at the base, and thus gradually gather in and draw the cuticle towards the center as it proceeded outwards.

Iodoform, dry or rubbed into the meshes of cheese-cloth or gauze, should be used sparingly with the first dressing, unless for special reasons septic infection was feared. This precaution should be taken with the primary dressings until the patient's tolerance of the drug could be well ascertained, since otherwise its toxic effects upon the system might be serious. If, however, it was found not to excite undue irritation or produce

other unpleasant results, its use would no doubt tend to keep the wound sweet and shorten the healing process. In ordinary cases, where there was little tension, the catgut ligature was perhaps the most useful; but where there was any resistance, or where it was desirable to retain the parts in apposition for a considerable length of time, silk or strong linen was preferable. For ligating the sac or omentum strong silk only should be used, because it was the most reliable, and if first rendered thoroughly antiseptic, it could be safely buried in the tissues without giving rise to irritation or ulceration.

It was seldom indeed that hæmorrhage would occasion any difficulty in this operation; but in any case where the ordinary resources failed to control the bleeding, or where the two parts of a large divided wound retracted, the temporary transfixion ligature would be found invaluable. Having applied this, one could go on with the operation, leisurely seeking out and securing the bleeding points; when the temporary stitch might be removed.

The only immediate dangers in the operation, other than those which had been considered, were shock and exhaustion. Having given some attention to these subjects, he stated that he would decline to operate only on those who were bordering on the moribund state, especially those in profound shock or deeply narcotized and the very old. In conclusion, Dr. Manley said that while there could be no doubt that the McBurney operation was generally successful, and that it was the easiest of performance, the safest from septic infection, and the least liable to be followed by relapse, of all others, the consummation of this admirable procedure, marking as it did a new era in herniotomy, would not have been possible without the light shed upon abdominal surgery by Marion Sims, and without the discoveries of Pasteur and Lister in bacteriology and antiseptics.

In the discussion which followed the paper Dr. George Huntington, who has assisted Dr. McBurney in a number of his operations at the Roosevelt Hospital, said that as to the approximation of the integument and the deeper structures—the conjoined tendon and the transversalis fascia—it was for the purpose of more readily accomplishing this that Dr. McBurney advocated the passage of lateral tension sutures; and it was found that by the careful adjustment of these tension sutures very satisfactory results were obtained. He said he should be somewhat afraid of leaving so large a wound without any sutures, as suggested by Dr. Manley, in the case of certain very fat subjects, for the reason that, on account of its large size, there would seem to be a probability of the cicatrix resulting being rather weak.

Before the Association adjourned Dr. J. G. Truax made a motion, which was afterwards car-

ried unanimously, that a committee should be appointed by the Chair for the purpose of conferring with the New York Board of Health with a view to securing a more perfect registration of births, than is now made. In the case of the deaths, he said, the registration was complete, because no body could be interred or removed from the city without a written permit from the Health Department; but it was notorious that the registration of births was at present very incomplete.

In seconding the motion, Dr. Alfred L. Carroll said that to judge from the New York vital statistics, as published every week, one would suppose, from the preponderance of the deaths over the births reported, that the population of the city was rapidly diminishing. The simple explanation of this was, that a very considerable proportion of the births were never reported at all; and this was due principally to the fact that nearly 40 per cent. of confinements were not attended by registered physicians or midwives. Some time ago, when he was Secretary of the New York State Board of Health, he had carefully investigated the registration of vital statistics in the principal countries of Europe, and he found that in Great Britain and Germany, where the records of births were very complete, the onus of reporting all births was placed upon the parents, or, in the event of the death of the latter, upon the guardians. Through his efforts the law had now been so amended as to make this the case also throughout the State of New York; but this did not apply to the large cities, like New York, which were governed by their own sanitary codes. At present, therefore, the vital statistics of this city were absolutely worthless.

MISCELLANY.

THE 75,000 EDITION.—The *Maryland Medical Journal* says: THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION deserves great credit for the enormous extra edition of 75,000, containing among other things a full programme of the next annual meeting at Newport, with a short guide to that beautiful resort, as well as an announcement of all the medical schools of the United States.

THE EXAMINING BOARD of the Marine-Hospital Service, at their last session examined twenty-seven candidates. The following gentlemen passed: Drs. Groenevald, of Louisiana, Young and Brown, of Virginia, and Stenson, of Maryland.

PHYSICIAN WANTED.—We have received a letter from Mr. T. L. Martin, of Pleasant View, Ind., asking to be placed in communication with a good physician seeking a country location. Any of our readers desirous of making a change should communicate with him.

CORRIGENDA.

IN THE JOURNAL of June 5, page 795, appears an article on "Temperament," by Dr. S. Edwin Solly; for "Helling," read *Helling*. In the issue of January 10, 1889, p. 84, for "W. W. Skinner, M.D., of Peoria, Ill.," read W. W. Skinner, M.D., of New York.
